## PREFACE TO FIFTH EDITION

SINCE the last edition of this little book was published in 1912 the most noteworthy contribution to genetical studies has come from the American school. In the fruit-fly, *Drosophila*, they have found unusually favourable material with which to work, and they have exploited the advantages it offers with energy and acumen. Their object has been to connect the phenomena of heredity with the visible material basis of the chromosomes of the living cell. Indeed, Professor Morgan has declared that, as the result of these researches, the problem of heredity has been solved. While admitting the very high value and interest of the work I am not prepared to subscribe to this dictum. I have tried, however, to present the position of the supporters of the chromosome theory, in order that those who wish to may make themselves acquainted with what is, at the present moment, the most keenly discussed question in heredity. This has necessitated the

addition of two chapters, with a corresponding increase in the number of Plates and Figures. Several chapters also have been rewritten. To those who helped me in connection with the illustrations to the earlier editions I wish to repeat my thanks. In the present issue they are also due to Professor Morgan for so kindly providing the material out of which Figures 31 and 32 have been constructed.

## CHAPTER I

### THE PROBLEM

A CURIOUS thing in the history of human thought, so far as literature reveals it to us, is the strange lack of interest shown in one of the most interesting of all human relationships. Few if any of the more primitive peoples seem to have attempted to define the part played by either parent in the formation of the offspring, or to have assigned peculiar powers of transmission to them, even in the vaguest way. For ages man must have been more or less consciously improving his domesticated races of animals and plants, yet it is not until the time of Aristotle that we have clear evidence of any hypothesis to account for these phenomena of heredity. The production of offspring by man was then held to be similar to the production of a crop from seed. The seed came from the man, the woman provided the soil. This remained the generally accepted view for many centuries, and it was not until the recognition of woman as more than a passive agent that the physical basis of heredity became established. That recognition was effected by the microscope, for only with its advent was actual observation of the minute

sexual cells made possible. After more than a hundred years of conflict lasting until the end of the eighteenth century, scientific men settled down to the view that each of the sexes makes a definite material contribution to the offspring produced by their joint efforts. Among animals the female contributes the ovum and the male the spermatozoon; among higher plants the corresponding cells are borne by the ovules and pollen grains.

As a general rule it may be stated that the reproductive cells produced by the female are relatively large and without the power of independent movement. In addition to the actual living substance which is to take part in the formation of a new individual, the ova are more or less heavily loaded with the yolk substance that is to provide for the nutrition of the developing embryo during the early stages of its existence. The size of the ova varies enormously in different animals. In birds and reptiles, where the contents of the egg form the sole resources of the developing young, they are very large in comparison with the size of the animal which lays them. In mammals, on the other hand, where the young are parasitic upon the mother during the earlier stages of their growth, the eggs are minute and only contain the small amount of yolk that enables them to reach the stage at which they develop the processes for attaching themselves to the wall of the maternal uterus. But whatever the differences in the size and appearance of the ova produced by different animals, they are all comparable in that each is a distinct and separate sexual cell which, as a rule, is unable to develop

into a new individual of its species unless it is fertilised by union with a sexual cell produced by the male.

The male sexual cells are always of microscopic size and are produced in the generative gland or testis in exceedingly large numbers. In addition to their minuter size they differ from the ova in their power of active movement. Animals present various mechanisms by which the sexual elements may be brought into juxtaposition, but in all cases some distance must be traversed in a fluid or semi-fluid medium (frequently within the body of the female parent) before the necessary fusion can occur. To accomplish this latter end of its journey the spermatozoon is endowed with some form of motile apparatus, and this frequently takes the form of a long flagellum, or whip-like process, by the lashing of which the little creature propels itself much as a tadpole with its tail.

In plants as in animals the female cells are larger than the male cells, though the disparity in size is not nearly so marked. Still they are always relatively minute since the circumstances of their development as parasites upon the mother plant render it unnecessary for them to possess any great supply of food yolk. The ovules are found surrounded by maternal tissue in the ovary, but through the stigma and down the pistil a potential passage is left for the male cell. The majority of flowers are hermaphrodite, and in many cases they are also self-fertilising. The anthers burst and the contained pollen grains are then shed upon the stigma. When this happens, the pollen cell slips

through a little hole in its coat and bores its way down the stigma to reach an ovule in the ovary. Complete fusion occurs, and the minute embryo of a new plant immediately results. But for some time it is incapable of leading a separate existence, and, like the embryo mammal, it lives as a parasite upon its parent. By the parent it is provided with a protective wrapping, the seed coat, and beneath this the little embryo swells until it reaches a certain size, when as a ripe seed it severs its connection with the maternal organism. It is important to realise that the seed of a plant is not a sexual cell but a young individual which, except for the coat that it wears, belongs entirely to the next generation. It is with annual plants in some respects as with many butterflies. During one summer they are initiated by the union of two sexual cells and pass through certain stages of larval development—the butterfly as a caterpillar, the plant as a parasite upon its mother. As the summer draws to a close each passes into a resting-stage against the winter cold—the butterfly as a pupa and the plant as a seed, with the difference that while the caterpillar provides its own coat, that of the plant is provided by its mother. With the advent of spring both butterfly and plant emerge, become mature, and themselves ripen germ cells which give rise to a new generation.

Whatever the details of development one cardinal fact is clear. Except for the relatively rare instances of parthenogenesis a new individual, whether plant or animal, arises as the joint product of two sexual cells derived from individuals of different sexes. Such sexual cells, whether ova or spermatozoa,

are known by the general term of **gametes**, or marrying cells, and the individual formed by the fusion or yoking together of two gametes is spoken of as a **zygote**. Since a zygote arises from the yoking together of two separate gametes, the individual so formed must be regarded throughout its life as a double structure in which the components brought in by each of the gametes remain intimately fused in a form of partnership. But when the zygote in its turn comes to form gametes, the partnership is broken and the process is reversed. The component parts of the dual structure are resolved with the formation of a set of single structures, the gametes.

The life cycle of a species from among the higher plants or animals may be regarded as falling into three periods: (1) a period of isolation in the form of gametes, each a living unit incapable of further development without intimate association with another produced by the opposite sex; (2) a period of association in which two gametes become yoked together into a zygote, and react upon one another to give rise by a process of cell division to what we ordinarily term an individual with all its various attributes and properties; and (3) a period of dissociation when the single structured gametes separate out from that portion of the double structured zygote which constitutes its generative gland. What is the relation between gamete and zygote, between zygote and gamete? how are the properties of the zygote represented in the gamete, and in what manner are they distributed from the one to the other?—these are questions which serve to indicate

the nature of the problem underlying the process of heredity.

Owing to their peculiar power of growth and the relatively large size to which zygotes attain, many of their properties are appreciable by observation. The colour of an animal or of a flower, the shape of a seed, or the pattern on the wings of a moth, are all zygotic properties, and all capable of direct estimation. It is otherwise with the properties of gametes. While the difference between a black and a white fowl is sufficiently obvious, no one by inspection can tell the difference between the egg that will hatch into a black and that which will hatch into a white. Nor from a mass of pollen grains can anyone to-day pick out those that will produce white from those that will produce coloured flowers. Nevertheless, we know that in spite of apparent similarity there must exist fundamental differences among the gametes, even among those that spring from the same individual. At present our only way of appreciating those differences is to observe the properties of the zygotes which they form. And as it takes two gametes to form a zygote, we are in the position of attempting to decide the properties of two unknowns from one known. Fortunately the problem is not entirely one of simple mathematics. It can be attacked by the experimental method, and with what measure of success will appear in the following pages.

## CHAPTER II

### HISTORICAL

TO Gregor Mendel, monk and abbot, belongs the credit of founding the modern science of heredity. Through him there was brought into these problems an entirely new idea, an entirely fresh conception of the nature of living things. Born in 1822 of Austro-Silesian parentage, he early entered the monastery of Brünn, and there, in the seclusion of the cloister garden, he carried out with the common pea the series of experiments which has since become so famous. In 1865, after eight years' work, he published the results of his experiments in the *Proceedings of the Natural History Society of Briinn*, in a brief paper of some forty pages. But brief as it is, the importance of the results and the lucidity of the exposition will always give it high rank among the classics of biological literature. For thirty-five years Mendel's paper remained unknown, and it was not until 1900 that it was simultaneously discovered by several distinguished botanists. The causes of this curious neglect are not altogether without interest. •Hybridisation experiments before Mendel there had been in plenty. The classificatory work of Linnaeus in the latter half of the eighteenth

century had given a definite significance to the word species, and scientific men began to turn their attention to attempting to discover how species were related to one another. And one obvious way of attacking the problem was to cross different species together and see what happened. This was largely done during the earlier half of the nineteenth century, though such work was almost entirely confined to the botanists. Apart from the fact that plants lend themselves to hybridisation work more readily than animals, there was probably another reason why zoologists neglected this form of investigation. The field of zoology is a wider one than that of botany, presenting a far greater variety of type and structure. Partly owing to their importance in the study of medicine, and partly owing to their smaller numbers, the anatomy of the vegetable was far better known than that of the animal kingdom. It is, therefore, not surprising that the earlier part of the nineteenth century found the zoologists, under the influence of Cuvier and his pupils, devoting their entire energies to describing the anatomy of the new forms of animal life which careful search at home and fresh voyages of discovery abroad were continually bringing to light. During this period the zoologist had little inclination or inducement to carry on those investigations in hybridisation which were occupying the attention of some botanists. Nor did the efforts of the botanists afford much encouragement to such work, for in spite of the labour devoted to these experiments the results offered but a confused tangle of facts, contributing in no apparent way to the solution of the problem

for which they had been undertaken. After half a century of experimental hybridisation the determination of the relation of species and varieties to one another seemed as remote as ever. Then in 1859 came the *Origin of Species*, in which Darwin presented to the world a consistent theory to account for the manner in which one species might have arisen from another by a process of gradual evolution. Briefly put, that theory was as follows:—In any species of plant or animal the reproductive capacity tends to outrun the available food-supply, and the resulting competition leads to an inevitable struggle for existence. Of all the individuals born, only a portion, and that often a very small one, can survive to produce offspring. According to Darwin's theory, the nature of the surviving portion is not determined by chance alone. No two individuals of a species are precisely alike, and among the variations that occur some enable their possessors to cope more successfully with the competitive conditions under which they exist. In comparison with their less favoured brethren they have a better chance of surviving in the struggle for existence and, consequently, of leaving offspring. The argument is completed by the further assumption of a principle of heredity, in virtue of which offspring tend to resemble their parents more than other members of the species. Parents possessing a favourable variation tend to transmit that variation to their offspring, to some in greater, to others in less degree. Those possessing it in greater degree will again have a better chance of survival, and will transmit the favourable variation in even greater degree to

some of their offspring. A competitive struggle for existence working in combination with certain principles of variation and heredity results in a slow and continuous transformation of species through the operation of a process which Darwin termed natural selection.

The coherence and simplicity of the theory, supported as it was by the great array of facts which Darwin had patiently marshalled together, rapidly gained the enthusiastic support of the great majority of biologists. The problem of the relation of species at last appeared to be solved, and for the next forty years zoologists and botanists were busily engaged in classifying, by the light of Darwin's theory, the great masses of anatomical facts which had already accumulated, and in adding and classifying fresh ones. The study of comparative anatomy and embryology received a new stimulus, for with the acceptance of the theory of descent with modification it became incumbent upon the biologist to demonstrate the manner in which animals and plants differing widely in structure and appearance could be conceivably related to one another. Thenceforward the energies of both botanists and zoologists have been devoted to the construction of hypothetical pedigrees suggesting the various tracks of evolution by which one group of animals or plants may have arisen from another through a long-continued process of natural selection. The result of such work on the whole may be said to have shown that the diverse forms under which living things exist to-day, and have existed in the past so far as palaeontology can tell us, are consistent with the view that they are all

related by the community of descent which the accepted theory of evolution demands, though as to the exact course of descent for any particular group of animals there is often considerable diversity of opinion. It is obvious that all this work has little or nothing to do with the manner in which species are formed. Indeed, the effect of Darwin's *Origin of Species* was to divert attention from the way in which species originate. At the time that it was put forward his explanation appeared so satisfying that biologists accepted the notions of variation and heredity there set forth and ceased to take any further interest in the work of the hybridisers. Had Mendel's paper appeared a dozen years earlier it is difficult to believe that it could have failed to attract the attention it deserved. Coming as it did a few years after the publication of Darwin's great work, it found men's minds set at rest on the problems that he raised and their thoughts and energies directed to other matters.

Nevertheless, one interesting and noteworthy attempt to give greater precision to the term heredity was made about this time. Francis Galton, a cousin of Darwin, working upon data relating to the breeding of Basset hounds, found that he could express on a definite statistical scheme the proportion in which the different colours appeared in successive generations. Every individual was conceived of as possessing a definite heritage which might be expressed as unity. Of this,  $\frac{1}{2}$  was on the average derived from the two parents (*i.e.*  $\frac{1}{4}$  from each parent),  $\frac{1}{4}$  from the four grandparents,  $\frac{1}{8}$  from the eight great-grandparents, and so on. The *Law of Ancestral*

*Heredity*, as it was termed, expresses with fair accuracy some of the statistical phenomena relating to the transmission of characters in a mixed population. But the problem of the way in which characters are distributed from gamete to zygote and from zygote to gamete remained as before. Heredity is essentially a physiological problem, and though statistics may be suggestive in the initiation of experiment, it is upon the basis of experimental fact that progress must ultimately rest. For this reason, in spite of its ingenuity and originality, Galton's theory and the subsequent statistical work that has been founded upon it failed to give us any deeper insight into the nature of the hereditary process.

While Galton was working in England the German zoologist, August Weismann, was elaborating the complicated theory of heredity which eventually appeared in his work on *The Germplasm* (1885), a book which will be remembered for one notable contribution to the subject. Until the publication of Weismann's work it had been generally accepted that the modifications brought about in the individual during its lifetime, through the varying conditions of nutrition and environment, could be transmitted to the offspring. In this biologists were but following Darwin, who held that the changes in the parent resulting from increased use or disuse of any part or organ were passed on to the children. Weismann's theory involved the conception of a sharp cleavage between the general body tissues or somatoplasm and the reproductive glands or germplasm. The individual was merely a carrier for the essential germplasm whose properties had been determined

long before he was capable of leading a separate existence. As this conception ran counter to the possibility of the inheritance of "acquired characters," Weismann challenged the evidence upon which it rested and showed that it broke down wherever it was critically examined. By thus compelling biologists to revise their ideas as to the inherited effects of use and disuse, Weismann rendered a valuable service to the study of genetics and did much to clear the way for subsequent research.

A further important step was taken in 1895, when Bateson once more drew attention to the problem of the origin of species, and questioned whether the accepted ideas of variation and heredity were after all in consonance with the facts. Speaking generally, species do not grade gradually from one to the other, but the differences between them are sharp and specific. Whence comes this prevalence of discontinuity if the process by which they have arisen is one of accumulation of minute and almost imperceptible differences? Why are not intermediates of all sorts more abundantly produced in nature than is actually known to be the case? Bateson saw that if we are ever to answer this question we must have more definite knowledge of the nature of variation and of the nature of the hereditary process by which these variations are transmitted. And the best way to obtain that knowledge was to let the dead alone and to return to the study of the living. It was true that the past record of experimental breeding had been mainly one of disappointment. It was true also that there was no tangible clue by which experiments might be directed in the present.

Nevertheless in this kind of work alone seemed there any promise of ultimate success.

A few years later appeared the first volume of de Vries' remarkable book on *The Mutation Theory*. From a prolonged study of the evening primrose (*Oenothera*) de Vries concluded that new varieties suddenly arose from older ones by sudden sharp steps or mutations, and not by any process involving the gradual accumulation of minute differences. The number of striking cases from among widely different plants which he was able to bring forward went far to convincing biologists that discontinuity in variation was a more widespread phenomenon than had hitherto been suspected, and not a few began to question whether the account of the mode of evolution so generally accepted for forty years was after all the true account. Such, in brief, was the outlook in the central problem of biology at the time of the rediscovery of Mendel's work.

## CHAPTER III

### MENDEL'S WORK

THE task that Mendel set before himself was to gain some clear conception of the manner in which the definite and fixed varieties found within a species are related to one another, and he realised at the outset that the best chance of success lay in working with material of such a nature as to reduce the problem to its simplest terms. He decided that the plant with which he was to work must be normally self-fertilising and unlikely to be crossed through the interference of insects, while at the same time it must possess definite fixed varieties which bred true to type. In the common pea (*Pisum sativum*) he found the plant he sought. A hardy annual, prolific, easily worked, *Pisum* has a further advantage in that the insects which normally visit flowers are unable to gather pollen from it and so to bring about cross-fertilisation. At the same time it exists in a number of strains presenting well-marked and fixed differences. The flowers may be purple, or red, or white; the plants may be tall or dwarf; the ripe seeds may be yellow or green, round or wrinkled,—such are a few of the

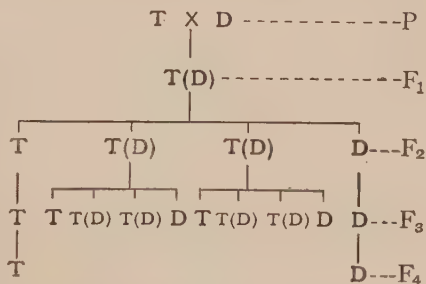

characters in which the various races of peas differ from one another.

In planning his crossing experiments Mendel adopted an attitude which marked him off sharply from the earlier hybridisers. He realised that their failure to elucidate any general principle of heredity from the results of cross-fertilisation was due to their not having concentrated upon particular characters or traced them carefully through a sequence of generations. That source of failure he was careful to avoid, and throughout his experiments he crossed plants presenting sharply contrasted characters, and devoted his efforts to observing the behaviour of these characters in successive generations. Thus in one series of experiments he concentrated his attention on the transmission of the characters tallness and dwarfness, neglecting in so far as these experiments were concerned any other characters in which the parent plants might differ from one another. For this purpose he chose two strains of peas, one of about 6 feet in height, and another of about  $1\frac{1}{2}$  feet. Previous testing had shown that each strain bred true to its peculiar height. These two strains were artificially crossed<sup>1</sup> with one another, and it was found to make no difference which was used as the pollen parent and which was used as the ovule parent. In either case the result was the same. The result of crossing tall with dwarf was in every case nothing but tall, as tall or even a little taller than the tall parent. For this reason Mendel termed tallness the **dominant** and dwarfness the

<sup>1</sup> Cf. note on p. 213.

recessive character. The next stage was to collect and sow the seeds of these tall hybrids. Such seeds in the following year gave rise to a mixed generation consisting of tall and dwarfs *but no intermediates*. By raising a considerable number of such plants Mendel was able to establish the fact that the number of tall which occurred in this generation was almost exactly three times as great as the number of the dwarfs. As in the previous year, seeds were carefully collected from this, the second hybrid generation, and in every case *the seeds from each individual plant were harvested separately and separately sown in the following year*. By this respect for the individuality of the different plants, however closely they resembled one another, Mendel found the clue that had eluded the efforts of all his predecessors. The seeds collected from the dwarf recessives bred true, giving nothing but dwarfs. And this was true for every dwarf tested. But with the tall it was quite otherwise. Although indistinguishable in appearance, some of them bred true, while others behaved like the original tall hybrids, giving a generation consisting of tall and dwarfs in the proportion of three of the former to one of the latter. Counting showed that the number of the tall which gave dwarfs was double that of the tall which bred true.

If we denote a dwarf plant as D, a true breeding tall plant as T, and a tall which gives both tall and dwarfs in the ratio 3 : 1 as T(D), the result of these experiments may be briefly summarised in the foregoing scheme.<sup>1</sup>

Mendel experimented with other pairs of contrasted characters and found that in every instance they followed the same scheme of inheritance. Thus coloured flowers were dominant to white, in the ripe seeds yellow was dominant to green, and round shape was dominant to wrinkled, and so on. In every case where the inheritance of an alternative pair of characters was concerned the effect of the cross in successive generations was to produce three and only three different sorts of individuals, viz. dominants which bred true, dominants which gave both dominant and recessive offspring in the ratio 3 : 1, and recessives which always bred true. Having determined a general scheme of inheritance which experiment showed to hold good for each of the seven pairs of alternative characters with which he worked, Mendel set himself to providing a theoretical interpretation of this scheme which, as he clearly realised, must be in terms of germ cells. He conceived of the gametes as bearers of something capable of giving rise to the characters of the plant, but he regarded any individual gamete as being able to carry one and one only of any alternative pair of characters. A given gamete could carry tallness *or* dwarfness, but not both. The two were mutually

<sup>1</sup> It has been found convenient to denote the various generations resulting from a cross by the signs  $F_1$ ,  $F_2$ ,  $F_3$ , etc.  $F_1$  on this system denotes the first filial generation,  $F_2$  the second filial generation produced by two parents belonging to the  $F_1$  generation, and so on.

exclusive so far as the gamete was concerned. It must be pure for one or the other of such a pair, and this conception of the purity of the gametes is the most essential part of Mendel's theory.

We may now proceed with the help of the accompanying scheme (Fig. 1) to deduce the results that should

flow from Mendel's conception of the nature of the gametes, and to see how far they are in accordance with the facts. Since the original tall plant belonged to a strain which bred true, all the gametes produced by it must bear the tall character. Similarly all the gametes of the original dwarf plant must

FIG. 1.

Scheme of inheritance in the cross of tall with dwarf pea. Gametes represented by small and zygotes by larger circles.

bear the dwarf character. A cross between these two means the union of a gamete containing tallness with one bearing dwarfness. Owing to the completely dominant nature of the tall character, such a plant is in appearance indistinguishable from the pure tall, but it differs markedly from it in the nature of the gametes to which it gives rise. When the formation of the gametes occurs, the elements representing dwarfness

and tallness **segregate** from one another, so that half of the gametes produced contain the one, and half contain the other of these two elements. For on hypothesis every gamete must be pure for one or other of these two characters. And this is true for the ovules as well as for the pollen grains. Such hybrid  $F_1$  plants, therefore, must produce a series of ovules consisting of those bearing tallness and those bearing dwarfness, and must produce them in equal numbers. And similarly for the pollen grains. We may now calculate what should happen when such a series of pollen grains meets such a series of ovules, *i.e.* the nature of the generation that should be produced when the hybrid is allowed to fertilise itself. Let us suppose that there are  $4x$  ovules so that  $2x$  are "tall" and  $2x$  are "dwarf." These are brought in contact with a mass of pollen grains of which half are "tall" and half are "dwarf." It is obvious that a "tall" ovule has an equal chance of being fertilised by a "tall" or a "dwarf" pollen grain. Hence of our  $2x$  "tall" ovules,  $x$  will be fertilised by "tall" pollen grains and  $x$  will be fertilised by "dwarf" pollen grains. The former must give rise to tall plants, and since the dwarf character has been entirely eliminated from them they must in the future breed true. The latter must also give rise to tall plants, but since they carry also the recessive dwarf character they must when bred from produce both talls and dwarfs. Each of the  $2x$  dwarf ovules, again, has an equal chance of being fertilised by a "tall" or by a "dwarf" pollen grain. Hence  $x$  will give rise to tall plants carrying the recessive dwarf character, while  $x$  will produce

plants from which the tall character has been eliminated, *i.e.* to pure recessive dwarfs. Consequently from the  $4x$  ovules of the self-fertilised hybrid we ought to obtain  $3x$  tall and  $x$  dwarf plants. And of the  $3x$  tall  $x$  should breed true to tallness, while the remaining  $2x$ , having been formed like the original hybrid by the union of a "tall" and a "dwarf" gamete, ought to behave like it when bred from and give tall and dwarfs in the ratio 3 : 1. Now this is precisely the result actually obtained by experiment (cf. p. 18), and the close accord of the experimental results with those deduced on the assumption of the purity of the gametes as enunciated by Mendel affords the strongest of arguments for regarding the nature of the gametes and their relation to the characters of the zygotes in the way that he has done.

It is possible to put the theory to a further test. The explanation of the 3 : 1 ratio of dominants and recessives in the  $F_2$  generation is regarded as due to the  $F_1$  individuals producing equal numbers of gametes bearing the dominant and recessive elements respectively. If now the  $F_1$  plant be crossed with the pure recessive, we are bringing together a series of gametes consisting of equal numbers of dominants and recessives with a series consisting solely of recessives. We ought from such a cross to obtain equal numbers of dominant and recessive individuals, and further, the dominants so produced ought all to give both dominants and recessives in the ratio 3 : 1 when they themselves are bred from. Both of these expectations were amply confirmed by experiment, and crossing with the recessive is now a

recognised way of testing whether a plant or animal bearing a dominant character is a pure dominant or an impure dominant which is carrying the recessive character. In the former case the offspring will be all of the dominant form, while in the latter they will consist on the average of equal numbers of dominants and recessives.

So far we have been concerned with the results obtained when two individuals differing in a single pair of characters are crossed together and with the interpretation of those results. But Mendel also used plants which differed in more than a single pair of differentiating characters. In such cases he found that each pair of characters followed the same definite rule, but that the inheritance of each pair was absolutely independent of the other. Thus, for example, when a tall plant bearing coloured flowers was crossed with a dwarf plant bearing white flowers the resulting hybrid was a tall plant with coloured flowers. For coloured flowers are dominant to white, and tallness is dominant to dwarfness. In the succeeding generation there are plants with coloured flowers and plants with white flowers in the proportion of 3 : 1, and at the same time tall plants and dwarf plants in the same proportion. Hence the chances that a tall plant will have coloured flowers are three times as great as its chance of having white flowers. And this is also true for the dwarf plants. As the result of this cross, therefore, we should expect an  $F_2$  generation consisting of four classes, viz. coloured tall, white tall, coloured dwarf, and white dwarf, and we should further expect these four forms to appear in the ratio of

9 coloured tall, 3 white tall, 3 coloured dwarf, and 1 white dwarf. For this is the only ratio which satisfies the conditions that the tall should be to the dwarf as 3 : 1, and at the same time the coloured should be to the white as 3 : 1. And these are the proportions that Mendel found to obtain actually in his experiments. Put in a more general form, it may be stated that when two individuals are crossed which differ in two pairs of differentiating characters the hybrids ( $F_1$ ) are all of the same form, exhibiting the dominant character of each of the two pairs, while the  $F_2$  generation produced by such hybrids consists on the average of 9 showing both dominants, 3 showing one dominant and one recessive, 3 showing the other dominant and the other recessive, and 1 showing both recessive characters. And, as Mendel pointed out, the principle may be extended indefinitely. If, for example, the parents differ in three pair of characters  $A$ ,  $B$ , and  $C$  respectively dominant to  $a$ ,  $b$ , and  $c$ , the  $F_1$  individuals will be all of the form  $ABC$ , while the  $F_2$  generation will consist of 27  $ABC$ , 9  $ABc$ , 9  $AbC$ , 9  $aBC$ , 3  $Abc$ , 3  $aBc$ , 3  $abC$ , and 1  $abc$ . When individuals differing in a number of alternative characters are crossed together, the hybrid generation, provided that the original parents were of pure strains, consists of plants of the same form; but when these are bred from, a redistribution of the various characters occurs. That redistribution follows the same definite rule for each character, and if the constitution of the original parents be known, the nature of the  $F_2$  generation, *i.e.* the number of possible forms and the proportions in which they

occur, can be readily calculated. Moreover, as Mendel showed, we can calculate also the chances of any given form breeding true. To this point, however, we shall return later.

Of Mendel's experiments with beans it is sufficient to say here that they corroborated his more ample work with peas. He is also known to have made experiments with many other plants, and a few of his results are incidentally given in his series of letters to Nägeli the botanist. To the breeding and crossing of bees he also devoted much time and attention, but unhappily the record of these experiments appears to have been lost. The only other published work that we possess dealing with heredity is a brief paper on some crossing experiments with the Hawk-weeds (*Hieracium*), a genus that he chose for working with because of the enormous number of forms under which it naturally exists. By crossing together the more distinct varieties, he evidently hoped to produce some of these numerous wild forms, and so throw light upon their origin and nature. In this hope he was disappointed. Owing in part to the great technical difficulties attending the cross-fertilisation of these flowers he succeeded in obtaining very few hybrids. Moreover, the behaviour of those which he did obtain was quite contrary to what he had found in the peas. Instead of giving a variety of forms in the  $F_2$  generation, they bred true and continued to do so as long as they were kept under observation. More recent research has shown that this is due to a peculiar form of parthenogenesis (cf. p. 157), and not to any failure of the characters to separate clearly from one another in the gametes.

Mendel, however, could not have known of this, and his inability to discover in *Hieracium* any indication of the rule which he had found to hold good for both peas and beans must have been a source of considerable disappointment. Whether for this reason, or owing to the utter neglect of his work by the scientific world, Mendel gave up his experimental researches during the latter part of his life. His closing years were shadowed with ill-health and embittered by a controversy with the Government on a question of the rights of his monastery. He died of Bright's disease in 1884.

*Note.*—Shortly after the rediscovery of Mendel's paper a need was felt for terms of a general nature to express the constitution of individuals in respect of inherited characters, and Bateson accordingly proposed the words **homozygote** and **heterozygote**. An individual is said to be homozygous for a given character when it has been formed by two gametes each bearing the character, and all the gametes of a homozygote bear the character in respect of which it is homozygous. When, however, the zygote is formed by two gametes of which one bears the given character while the other does not, it is said to be heterozygous for the character in question, and only half the gametes produced by such a heterozygote bear the character. An individual may be homozygous for one or more characters, and at the same time may be heterozygous for others.

## CHAPTER IV

### THE PRESENCE AND ABSENCE THEORY

IT was fortunate for the development of biological science that the rediscovery of Mendel's work found a small group of biologists deeply interested in the problems of heredity, and themselves engaged in experimental breeding. To these men the extraordinary significance of the discovery was at once apparent. From their experiments, undertaken in ignorance of Mendel's paper, de Vries, Correns, and Tschermak were able to confirm his results in peas and other plants, while Bateson was the first to demonstrate their application to animals. Thenceforward the record has been one of steady progress, and the result of ten years' work has been to establish more and more firmly the fundamental nature of Mendel's discovery. The scheme of inheritance, which he was the first to enunciate, has been found to hold good for such diverse things as height, hairiness, and flower colour and flower form in plants, the shape of pollen grains, and the structure of fruits; while among animals the coat colour of mammals, the form of the feathers and of the comb in poultry, the waltzing habit of Japanese

mice, and eye colour in man are but a few examples of the diversity of characters which all follow the same law of transmission. And as time went on many cases which at first seemed to fall without the scheme have been gradually brought into line in the light of fuller knowledge. Some of these will be

FIG. 2.

A wing feather and a contour feather of an ordinary and a silky fowl. The peculiar ragged appearance of the silky feathers is due to the absence of the little hooks or barbules which hold the barbs together. The silky condition is recessive.

dealt with in the succeeding chapters of this book. Meanwhile we may concern ourselves with the single modification of Mendel's original views which has arisen out of more ample knowledge.

As we have already seen, Mendel considered that in the gamete there was either a definite something corresponding to the dominant character or a definite something corresponding to the recessive character,

and that these somethings whatever they were could not coexist in any single gamete. For these somethings we shall in future use the term **factor**. The factor, then, is what corresponds in the gamete to the **unit-character** that appears in some shape or other in the development of the zygote. Tallness in the pea is a unit-character, and the gametes in which it is

FIG. 3.

Two double and an ordinary single primula flower. This form of double is recessive to the single.

represented are said to contain the factor for tallness. Beyond their existence in the gamete and their mode of transmission we make no suggestion as to the nature of these factors.<sup>1</sup>

On Mendel's view there was a factor correspond-

<sup>1</sup> Though in this particular instance in the pea there would appear to be a strict correspondence between a unit-character and a factor, it must not be taken that this is always so clear. As will appear later, the character in which two plants or animals of the same family differ from one another may depend upon two or even more factors.

ing to the dominant character and another factor corresponding to the recessive character of each alternative pair of unit-characters, and the characters were alternative because no gamete could carry more than one of the two factors belonging to the alternative pair. On the other hand, Mendel supposed that it always carried either one or the other of such a pair. As experimental work proceeded, it soon became clear that there were cases which could not be expressed in terms of this conception. The nature of the difficulty and the way in which it was met will perhaps be best understood by considering a set of experiments in which it occurred. Many of the different breeds of poultry are characterised by a particular form of comb, and in certain cases the inheritance of these has been carefully worked out. It was shown that the rose comb (Fig. 4, B) with its flattened papillated upper surface and backwardly projecting pike was dominant in the ordinary way to the deeply serrated high single comb (Fig. 4, C) which is characteristic of the Mediterranean races. Experiment also showed that the pea comb (Fig. 4, A), a form with a low central and two well-developed lateral ridges such as is found in Indian game, behaves as a simple dominant to the single comb. The interesting question arose as to what would happen when the rose and the pea, two forms each dominant to the same third form, were mated together. It seemed reasonable to suppose that things which were alternative to the same thing would be alternative to one another—that either rose or pea would dominate in the hybrids, and that the  $F_2$  generation would consist of dominants and recessives in the ratio 3 : 1. The

result of the experiment was, however, very different. The cross rose  $\times$  pea led to the production of a comb quite unlike either of them. This, the so-called walnut comb (Fig. 4, D), from its resemblance to

FIG. 4.

Fowls' combs. A, pea ; B, rose ; C, single ; D, walnut.

the half of a walnut, is a type of comb which is normally characteristic of the Malay fowl. Moreover, when these  $F_1$  birds were bred together, a further unlooked-for result was obtained. As was expected, there appeared in the  $F_2$  generation the three forms walnut, rose, and pea. But there also appeared

a definite proportion of single combed birds, and among many hundreds of chickens bred in this way the proportions in which the four forms walnut, rose, pea, and single appeared was 9 : 3 : 3 : 1. Now this, as Mendel showed, is the ratio found in an  $F_2$  generation when the original parents differ in two pairs of alternative characters, and from the proportions in which the different forms of comb occur we must infer that the walnut contains both dominants, the rose and the pea one dominant each, while the single is pure for both recessive characters. This accorded with subse-

quent breeding experiments, for the singles bred perfectly true as soon as they had once made their appearance. So far the case is clear. The difficulty comes when we attempt to define these two pairs of characters. How are we to express the fact that while single behaves as a simple recessive to either pure rose or to pure pea, it can yet appear in  $F_2$  from a cross between these two pure forms, though neither of them should, on Mendel's view, contain the single? An explanation which covers the facts in a simple way is that which has been termed the "Presence and Absence" theory. On this theory the dominant character of an alternative pair owes its dominance to the presence of a factor which is absent in the recessive. The tall pea is tall owing to the presence in it of the factor for tallness, but in the absence of this factor the pea

remains a dwarf. All peas are dwarf, but the tall is a dwarf plus a factor which turns it into a tall. Instead of the characters of an alternative pair being due to two separate factors, we now regard them as the expression of the only two possible states of a single factor, viz. its presence or its absence. The conception will probably become clearer if we follow its application in detail to the case of the fowls' combs. In this case we are concerned with the transmission of the two factors, rose ( $R$ ), and pea ( $P$ ), the presence of each of which is alternative to its absence. The rose-combed bird contains the factor for rose but not that for pea, and the pea-combed bird contains the factor for pea but not that for rose. When both factors are present in a bird, as in the hybrid made by crossing rose with pea, the result is a walnut. For convenience of argument we may denote the presence of a given factor by a capital letter and its absence by the corresponding small letter. The use of the small letter is merely a symbolic way of intimating that a particular factor is absent in a gamete or zygote. Represented thus the zygotic constitution of a pure rose-combed bird is  $RRpp$ ; for it has been formed by the union of two gametes both of which contained  $R$  but not  $P$ . Similarly we may denote the pure pea-combed bird as  $rrPP$ . On crossing the rose with the pea, union occurs between a gamete  $Rp$  and a gamete  $rP$ , resulting in the formation of a heterozygote of the constitution  $RrPp$ . The use of the small letters here informs us that such a zygote contains only a single dose of each of the factors  $R$  and  $P$ , although, of course, it is possible for a zygote, if made in a

suitable way, to have a double dose of any factor. Now when such a bird comes to form gametes a separation takes place between the part of the zygotic cell containing  $R$  and the part which does not contain it ( $r$ ). Half of its gametes, therefore, will contain  $R$  and the other half will be without it ( $r$ ). Similarly half of its gametes will contain  $P$  and the other half will be without it ( $p$ ). It is obvious that the chances of  $R$  being distributed to a gamete with or without  $P$  are equal. Hence the gametes containing  $R$  will be of two sorts,  $PR$  and  $Rp$ , and these will be produced in equal numbers. Similarly the gametes without  $R$  will also be of two sorts,  $rP$  and  $rp$ , and these, again, will be produced in equal numbers. Each of the hybrid walnut-combed birds, therefore, gives rise to a series consisting of equal numbers of gametes of the four different types  $RP$ ,  $Rp$ ,  $rP$ , and  $rp$ ; and the breeding together of such  $F_1$  birds means the bringing together of two such series of gametes. When this happens an ovum of any one of the four types has an equal chance of being fertilised by a spermatozoon of any one of the four types. A convenient and simple method of demonstrating what happens under such circumstances is the method sometimes termed the "chessboard" method. For two series each consisting of four different types of gamete we require a square divided up into 16 parts. The four terms of the gametic series are first written horizontally across the four sets of four squares, so that the series is repeated four times. It is then written vertically four times, care being taken to keep to the same order. In this simple mechanical way all

the possible combinations are represented and in their proper proportions. Fig. 5 shows the result of applying this method to our series  $RP$ ,  $Rp$ ,  $rP$ ,  $rp$ , and the 16 squares represent the different kinds of zygotes formed and the proportions in which they occur. As the figure shows, 9 zygotes contain both  $R$  and  $P$ , having a double or a single dose of either

$RP$ $RP$ Walnut	$RP$ $Rp$ Walnut	$RP$ $rP$ Walnut	$RP$ $rp$ Walnut
$Rp$ $RP$ Walnut	$Rp$ $Rp$ Rose	$Rp$ $rP$ Walnut	$Rp$ $rp$ Rose
$rP$ $RP$ Walnut	$rP$ $Rp$ Walnut	$rP$ $rP$ Pea	$rP$ $rp$ Pea
$rp$ $RP$ Walnut	$rp$ $Rp$ Rose	$rp$ $rP$ Pea	$rp$ $rp$ Single

FIG. 5.

or both of these factors. Such birds must be all walnut combed. Three out of the 16 zygotes contain  $R$  but not  $P$ , and these must be rose-combed birds. Three, again, contain  $P$  but not  $R$ , and must be pea-combed birds. Finally one out of the 16 contains neither  $R$  nor  $P$ .

It cannot be rose—it cannot be pea. It must, therefore, be something else. As a matter of fact it is single. Why it should be single and not something else follows from what we already know about the behaviour of these various forms of comb. For rose is dominant to single; therefore on the Presence and Absence theory a rose is a single plus a factor which turns the single into a rose. If we could remove the “rose” factor from a rose-combed bird the underlying single would

come into view. Similarly a pea comb is a single plus a factor which turns the single into a pea, and a walnut is a single which possesses two additional modifying factors. Singleness, in fact, underlies all these combs, and if we write their zygotic constitution in full we must denote a walnut as *RRPPSS*, a rose as *RRppSS*, a pea as *rrPPSS*, and a single as *rrppSS*. The crossing of rose with pea results in a reshuffling of the factors concerned, and in accordance with the principle of segregation some zygotes are formed in which neither of the modifying factors *R* and *P* is present, and the single character can then become manifest.

The Presence and Absence theory is to-day generally accepted by students of these matters. Not only does it afford a simple explanation of the remarkable fact that in all cases of Mendelian inheritance we should be able to express our unit-characters in terms of alternative pairs, but, as we shall have occasion to refer to later, it suggests a clue as to the course by which the various domesticated varieties of plants and animals have arisen from their wild prototypes.

Before leaving this topic we may draw attention to some experiments which offer a pretty confirmation of the view that the rose comb is a single to which a modifying factor for roseness has been added. It was argued that if we could find a type of comb in which the factor for singleness was absent, then on crossing such a comb with a rose we ought, if singleness really underlies rose, to obtain some single combs in  $F_2$  from such a cross. Such a comb we had the good fortune to find in the

Breda fowl, a breed largely used in Holland. This fowl is usually spoken of as combless, for the place of the comb is taken by a covering of short bristle-like feathers (Fig. 6, D). In reality it possesses the

FIG. 6.

Fowls' combs. A and B,  $F_1$  hen from rose  $\times$  Breda; C, an  $F_1$  cock from the cross of single  $\times$  Breda; D, head of Breda cock.

vestige of a comb in the form of two minute lateral knobs of comb tissue. Characteristic also of this breed is the high development of the horny nostrils, a feature probably correlated with the almost complete absence of comb. The first step in the

experiment was to prove the absence of the factor for singleness in the Breda. On crossing Breda with single the  $F_1$  birds exhibit a large comb of the form of a double single comb in which the two portions are united anteriorly, but diverge from one another towards the back of the head (Fig. 6, C). The Breda contains an element of duplicity which is dominant to the simplicity of the ordinary single comb. But it cannot contain the factor for the single comb, because as soon as that is put into it by crossing with a single the comb assumes a large

size, and is totally distinct in appearance from its almost complete absence in the pure Breda. Now when the Breda is crossed with the rose duplicity is dominant to simplicity, and rose is dominant to lack of comb, and the  $F_1$  generation consists of birds possessing duplex rose combs (Fig. 6, A and B). On breeding such birds together we obtain a generation consisting of Bredas, duplex roses, roses, duplex singles, and singles. From our previous experiment we know that the singles could not have come from the Breda, since a Breda comb to which the factor for single has been added no longer remains a Breda.

Therefore it must have come from the rose, thus confirming our view that the rose is in reality a single comb which contains in addition a dominant modifying factor ( $R$ ) whose presence turns it into a rose. We shall take it, therefore, that there is good experimental evidence for the Presence and Absence theory. Of recent years, however, it has come in for a good deal of criticism in connection with a group of facts which will be dealt with in a later chapter. Whether the conceptions it involves are strictly true or not, it nevertheless provides us with a simple and convenient system of notation for our factors, and we shall express in terms of it the various cases which come up for discussion in succeeding chapters.

## CHAPTER V

### INTERACTION OF FACTORS

WE have now reached a point at which it is possible to formulate a definite conception of the living organism. A plant or animal is a living entity whose properties may in large measure be expressed in terms of unit-characters, and it is the possession of a greater or lesser number of such unit-characters that renders it possible for us to draw sharp distinctions between one individual and another. These unit-characters are represented by definite factors in the gamete which in the process of heredity behave as indivisible entities, and are distributed according to a definite scheme. The factor for this or that unit-character is either present in the gamete or it is not present. It must be there in its entirety or completely absent. Such at any rate is the view to which recent experiment has led us. But as to the nature of these factors, the conditions under which they exist in the gamete, and the manner in which they produce their specific effects in the zygote, we are at present almost completely in the dark.

The case of the fowls' combs opens up the important question of the extent to which the various factors can influence one another in the zygote.

The rose and the pea factors are separate entities, and each when present alone produces a perfectly distinct and characteristic effect upon the single comb, turning it into a rose or a pea as the case may be. But when both are present in the same zygote their combined effect is to produce the walnut comb, a comb which is quite distinct from either and in no sense intermediate between them. The question of the influence of factors upon one another did not present itself to Mendel because he worked with characters which affected different parts of the plant. It was unlikely that the factor which led to the production of colour in the flower would affect the shape of the pod, or that the height of the plant would be influenced by the presence or absence of the factor that determined the shape of the ripe seed. But when several factors can modify the same structure it is reasonable to suppose that they will influence one another in the effects which their simultaneous presence has upon the zygote. By themselves the pea and the rose factors each produce a definite modification of the single comb, but when both are present in the zygote, whether as a single or double dose, the modification that results is quite different from that produced by either when present alone. Thus we are led to the conception of characters which depend for their manifestation on more than one factor in the zygote, and in the present chapter we may consider a few of the phenomena which result from such interaction between separate and distinct factors.

One of the most interesting and instructive cases in which the interaction between separate factors has

been demonstrated is a case in the sweet-pea. All white sweet-peas breed true to whiteness. And generally speaking the result of crossing different whites is to produce nothing but whites whether in  $F_1$  or in succeeding generations. But there are certain strains of white sweet-peas which when crossed together produce only coloured flowers. The colour may be different in different cases, though for our present purpose we may take a case in which the colour is red. When such reds are allowed to self-fertilise themselves in the normal way and the seeds

sown, the resulting  $F_2$  generation consists of reds and whites, the former being rather more numerous than the latter in the proportion of 9 : 7. The raising of a further generation from the

seeds of these  $F_2$  plants shows that the whites always breed true to whiteness, but that different reds may behave differently. Some breed true, others give reds and whites in the ratio 3 : 1, while others, again, give reds and whites in the ratio 9 : 7. As in the case of the fowls' combs, this case may be interpreted in terms of the presence and absence of two factors. Red in the sweet-pea results from the interaction of two factors, and unless these are both present the red colour cannot appear. Each of the white parents carried one of the two factors whose interaction is necessary for the production of the red colour, and as a cross between them brings these two complementary factors together the  $F_1$  plants must all be red. As this case is of considerable

importance for the proper understanding of much that is to follow, and as it has been completely worked out, we shall consider it in some detail. Denoting these two colour factors by  $A$  and  $B$  respectively we may proceed to follow out the consequences of this cross. Since all the  $F_1$  plants were red the constitution of the parental whites must have been  $AAbb$  and  $aaBB$  respectively, and

their gametes consequently  $Ab$  and  $aB$ . The constitution of the  $F_1$  plants must, therefore, be  $AaBb$ . Such a plant being heterozygous for two factors produces a series of gametes of the four kinds  $AB$ ,

$Ab$ ,  $aB$ ,  $ab$ , and produces them in equal numbers (cf. p. 33). To obtain the various types of zygotes which are produced when such a series of pollen grains meets a similar series of ovules we may make use of the same "chessboard" system which we have already adopted in the case of the fowls' combs. An examination of this figure (Fig. 7) shows that 9 out of the 16 squares contain both  $A$  and  $B$ , while 7 contain either  $A$  or  $B$  alone, or neither. In other words, on this view of the nature of the two white sweet-peas we should in the  $F_2$  generation look for the appearance of coloured and

white flowers in the ratio 9:7. And this, as we have already seen, is what was actually found by experiment. Further examination of the figure shows that the coloured plants are not all of the same constitution, but are of four kinds with respect to their zygotic constitution, viz.  $AABB$ ,  $AABb$ ,  $AaBB$ , and  $AaBb$ .

Since  $AABB$  is homozygous for both  $A$  and  $B$ , all the gametes which it produces must contain both of these factors, and such a plant must therefore breed true to the red colour. A plant of the constitution  $AABb$  is homozygous for the factor  $A$ , but heterozygous for

$AB$ $AB$	$AB$ $Ab$	$AB$ $aB$	$AB$ $ab$
$Ab$ $AB$	$Ab$ $Ab$	$Ab$ $aB$	$Ab$ $ab$

$B$ . All of its gametes will contain  $A$ , but only one-half of them will contain  $B$ , i.e. it produces equal numbers of gametes  $AB$  and  $Ab$ . Two such series of gametes coming together must give a generation consisting of  $x$   $AABB$ ,  $2x$   $AABb$ , and  $x$   $AAbb$ , that is, reds and whites in the ratio 3:1. Lastly the red zygotes of the constitution  $AaBb$  have the same constitution as the original red made from the two whites, and must therefore when bred from give reds and whites in the ratio 9:7. The existence

of all these three sorts of reds was demonstrated by experiment, and the proportions in which they were met with tallied with the theoretical explanation.

The theory was further tested by an examination into the properties of the various  $F_2$  whites which come from a coloured plant that has itself been produced by the mating of two whites. As Fig. 7 shows, these are, in respect of their constitution, of five different kinds, viz.  $AAbb$ ,  $Aabb$ ,  $aaBB$ ,  $aaBb$ , and  $aabb$ . Since none of them produce anything but whites on self-fertilisation it was found necessary to test their properties in another way, and the method adopted was that of crossing them together. It is obvious that when this is done we should expect different results in different cases. Thus the cross between two whites of the constitution  $AAbb$  and  $aaBB$  should give nothing but coloured plants; for these two whites are of the same constitution as the original two whites from which the experiment started. On the other hand, the cross between a white of the constitution  $aabb$  and any other white can never give anything but whites. For no white contains both  $A$  and  $B$ , or it would not be white, and a plant of the constitution  $aabb$  cannot supply the complementary factor necessary for the production of colour. Again, two whites of the constitution  $Aabb$  and  $aaBb$  when crossed should give both coloured and white flowers, the latter being three times as numerous as the former. Without going into further detail it may be stated that the results of a long series of crosses between the various  $F_2$  whites accorded closely with the theoretical explanation.

From the evidence afforded by this exhaustive set of experiments it is impossible to resist the deduction that the appearance of colour in the sweet-pea depends upon the interaction of two factors which are independently transmitted according to the ordinary scheme of Mendelian inheritance. What these factors are is still an open question. Recent evidence of a chemical nature indicates that colour in a flower is due to the interaction of two definitive substances: (1) a colourless "chromogen," or colour basis; and (2) a ferment which behaves as an activator of the chromogen, and by inducing some process of oxidation, leads to the formation of a coloured substance. But whether these two bodies exist as such in the gametes, or whether in some other form we have as yet no means of deciding.

Since the elucidation of the nature of colour in the sweet-pea phenomena of a similar kind have been witnessed in other plants, notably in stocks, snapdragons, and orchids. Nor is this class of phenomena confined to plants. In the course of a series of experiments upon the plumage colour of poultry, indications were obtained that different white breeds did not always owe their whiteness to the same cause. Crosses were accordingly made between the white Silky fowl and a pure white strain derived from the white Dorking. Each of these had been previously shown to behave as a simple recessive to colour. When the two were crossed only fully coloured birds resulted. From analogy with the case of the sweet-pea it was anticipated that such  $F_1$  coloured birds when bred together would produce an  $F_2$  generation consisting

of coloured and white birds in the ratio 9:7, and when the experiment was made this was actually shown to be the case. With the growth of knowledge it is probable that further striking parallels of this nature between the plant and animal worlds will be met with.

Before quitting the subject of these experiments, attention may be drawn to the fact that the 9:7 ratio is in reality a 9:3:3:1 ratio in which the last three terms are indistinguishable owing to the special circumstances that neither factor can produce a visible effect without the co-operation of the other. And we may further emphasise the fact that although the two factors thus interact upon one another they are nevertheless transmitted quite independently and in accordance with the ordinary Mendelian scheme.

One of the earliest sets of experiments demonstrating the interaction of separate factors was that

made by the French zoologist Cuénot on the coat colours of mice. It was shown that in certain cases agouti, which is the colour of the ordinary wild grey mouse, behaves as a

dominant to the albino variety, *i.e.* the  $F_2$  generation from such a cross consists of agoutis and albinos in the ratio 3:1. But in other cases the cross between albino and agouti gave a different result. In the  $F_1$  generation appeared only agoutis as before, but the  $F_2$  generation consisted of three distinct types, viz.

agoutis, albinos, and blacks. Whence the sudden appearance of the new type? The answer is a simple one. The albino parent was really a black. But it lacked the factor without which the colour is unable to develop, and consequently it remained an albino. If we denote this factor by  $C$ , then the constitution of an albino must be  $cc$ , while that of a coloured animal may be  $CC$  or  $Cc$ , according as to whether it breeds true to colour or can throw albinos. Agouti was previously known to be a simple dominant to black, *i.e.* an agouti is a black rabbit plus an additional greying factor which modifies the black into agouti. This factor we will denote by  $G$ , and we will use  $B$  for the black factor. Our original agouti and albino parents we may therefore regard as in constitution  $CCGGBB$  and  $ccggBB$  respectively. Both of the parents are homozygous for black. The gametes produced by the two parents are  $CGB$  and  $cgB$ , and the constitution of the  $F_1$  animals must be  $CcGgBB$ . Being heterozygous for two factors they will produce four kinds of gametes in equal numbers, *viz.*  $CGB$ ,  $CgB$ ,  $cGB$ , and  $cgB$ . The results of the mating of two such similar series of gametes when the  $F_1$  animals are bred together we may determine by the usual "chessboard" method (Fig. 8). Out of the 16 squares 9 contain both  $C$  and  $G$  in addition to  $B$ . Such animals must be agoutis. Three squares contain  $C$  but not  $G$ . Such animals must be coloured, but as they do not contain the modifying agouti factor their colour will be black. The remaining four squares do not contain  $C$ , and in the absence of this colour-developing factor they must all be albinos. Theory demands that the three classes

agouti, black, and albino should appear in  $F_2$  in the ratio 9 : 3 : 4 ; experiment has shown that these are the only classes that appear, and that the proportions in which they are produced accord closely with the

CGB CGB Agouti	CGB CgB Agouti	CGB cGB Agouti	CGB cgB Agouti

FIG. 8.

Diagram to illustrate the nature of the  $F_2$  generation which may arise from the mating of agouti with albino in mice or rabbits.

theoretical expectation. Put briefly, then, the explanation of this case is that all the animals are black, and that we are dealing with the presence and absence of two factors, a colour developer ( $C$ ), and a colour modifier ( $G$ ), both acting, as it were, upon a substratum of black. The  $F_2$

generation really consists of the four classes agoutis, blacks, albino agoutis, and albino blacks in the ratio 9 : 3 : 3 : 1. But since in the absence of the colour developer  $C$  the colour modifier  $G$  can produce no visible result, the last two classes of the ratio are indistinguishable, and our  $F_2$  generation comes to consist of three classes in the ratio 9 : 3 : 4, instead of four classes in the ratio 9 : 3 : 3 : 1.

This explanation was further tested by experiments with the albinos. In an  $F_2$  family of this nature there ought to be three kinds, viz. albinos homozygous for  $G$  ( $ccGGBB$ ), albinos heterozygous

for  $G$  ( $ccGgBB$ ), and albinos without  $G$  ( $ccggBB$ ). These albinos are, as it were, like photographic plates, exposed but undeveloped. Their potentialities may be quite different, although they all look alike, but this can only be tested by treating them with a colour developer. In the case of the mice and rabbits the potentiality for which we wish to test is the presence or absence of the factor  $G$ , and in order to develop the colour we must introduce the factor  $C$ . Our developer, therefore, must contain  $C$  but not  $G$ . In other words, it must be a homozygous black mouse or rabbit,  $CCggBB$ . Since such an animal is pure for  $C$  it must, when mated with any of the albinos, produce only coloured offspring. And since it does not contain  $G$  the appearance of agoutis among its offspring must be attributed to the presence of  $G$  in the albino. Tested in this way the  $F_2$  albinos were proved, as was expected, to be of three kinds: (1) those which gave only agouti, *i.e.* which were homozygous for  $G$ ; (2) those which gave agoutis and blacks in approximately equal numbers, *i.e.* which were heterozygous for  $G$ ; and (3) those which gave only blacks, and therefore did not contain  $G$ .

Though albinos, whether mice, rabbits, rats, or other animals, breed true to albinism, and though albinism behaves as a simple recessive to colour, yet albinos may be of many different sorts. There are in fact just as many kinds of albinos as there are coloured forms—neither more nor less. And all these different kinds of albinos may breed together, transmitting the various colour factors according to the Mendelian scheme of inheritance, and yet the visible result will be nothing but albinos. Under

the mask of albinism is all the while occurring that segregation of the different colour factors which would result in all the varieties of coloured forms, if only the essential factor for colour development were present. But put in the developer by crossing with a pure coloured form and their variety of constitution can then at last become manifest.

So far we have dealt with cases in which the production of a character is dependent upon the interaction of two factors. But it may be that some characters require the simultaneous presence of a greater number of factors for their manifestation, and Miss Saunders has shown that there is a character in ten-week stocks which is unable to appear except through the interaction of three distinct factors. Coloured stocks may be either hoary with the leaves and stem covered by small hairs, or they may lack the hairy covering, in which case they are termed glabrous. Hoariness is dominant to glabrousness; that is to say, there is a definite factor which can turn the glabrous into a hoary plant when it is present. But in families where coloured and white stocks occur the white are always glabrous, while the coloured plants may or may not be hoary. Now colour in the stock as in the sweet-pea has been proved to be dependent upon the interaction of two separate factors. Hence hoariness depends upon three separate factors, and a stock cannot be hoary unless it contains the hoary factor in addition to the two colour factors. It requires the presence of all these three factors to produce the hoary character, though how this comes about we have not at present the least idea.

A somewhat different and less usual form of interaction between factors may be illustrated by a case in primulas recently worked out by Bateson and Gregory. Like the common primrose, the primula exhibits both pin-eyed and thrum-eyed varieties. In the former the style is long, and the centre of the eye is formed by the end of the stigma which more or less plugs up the opening of the corolla (cf. Fig. 9, A); in the latter the style is short and hidden by

FIG. 9.

Sections of primula flowers. The anthers are shown as black. A, "pin" form with long style and anthers set low down; B, "thrum" form with short style and anthers set higher up; C, homostyle form with anthers set low down as in "pin," but with short style. This form only occurs with the large eye.

the five anthers which spring from higher up in the corolla and form the centre of the eye (cf. Fig. 9, B). The greater part of the "eye" is formed by the greenish-yellow patches on each petal just at the opening of the corolla. In most primulas the eye is small, but there are some in which it is large and extends as a flush over a considerable part of the petals (Fig. 10). Experiments showed that these two pairs of characters behave in simple Mendelian fashion, short style (= "thrum") being dominant to long style (= "pin") and small eye dominant to

large. Besides the normal long and short styled forms, there occurs a third form, which has been termed homostyle. In this form the anthers are placed low down in the corolla tube as they are in the long-styled form, but the style remains short instead of reaching up to the corolla opening (Fig. 9, C). In the course of their experiments Bateson

FIG. 10.

Two primula flowers showing the extent of the small and of the large eye.

and Gregory crossed a large-eyed homostyle plant with a small-eyed thrum (= short style). The  $F_1$  plants were all short styled with small eyes. On self-fertilisation these gave an  $F_2$  generation consisting of four types, viz. short styled with small eyes, short styled with large eyes, *long styled* with small eyes, and *homostyled* with large eyes. The notable feature of this generation is the appearance of long-styled plants, which, however, occur only in association with the small eye. The proportions in which these four types appeared show that the presence or absence of but two factors is concerned, and at

the same time provide the key to the nature of the homostyled plants. These are potentially long styled, and the position of the anthers is that of normal long-styled plants, but owing to some interaction between the factors the style itself is unable to reach its full development unless the factor for the small eye is present. For this reason long-styled plants with

the large eye are always of the homostyle form. What the connecting-link between these apparently unrelated structures may be we cannot yet picture to ourselves, any more than we can picture the relation between flower colour and hairiness in stocks. It is evident, however, that the conception of the interaction of factors, besides clearing up much that is paradoxical in heredity, promises to indicate lines of research which may lead to valuable extensions in our knowledge of the way in which the various parts of the living organism are related to one another.

## CHAPTER VI

### REVERSION

AS soon as the idea was grasped that characters in plants and animals might be due to the interaction of complementary factors, it became evident that this threw clear light upon the hitherto puzzling phenomenon of reversion. We have already seen that in certain cases the cross between a black mouse or rabbit and an albino, each belonging to true breeding strains, might produce nothing but agoutis. In other words, the cross between the black and the white in certain instances results in a complete reversion to the wild grey form. Expressed in Mendelian terms, the production of the agouti was the necessary consequence of the meeting of the factors *C* and *G* in the same zygote. As soon as they are brought together, no matter in what way, the reversion is bound to occur. Reversion, therefore, in such cases we may regard as the bringing together of complementary factors which had somehow in the course of evolution become separated from one another. In the simplest cases, such as that of the black and the white rabbit, only two factors are concerned, and one of them is brought in from each of the two parents. But in

# PLATE I.

1, Yellow Dutch Rabbit; 2, Himalayan; 3, Agouti; (= grey)  $F_1$  reversion; 4-8,  $F_2$  types, viz: 4, Agouti; 5, Yellow; 6, Black; 7, Tortoiseshell; 8, Himalayan.

other cases the nature of the reversion may be more complicated owing to a larger number of factors being concerned, though the general principle remains the same. Careful breeding from the reversions will enable us in each case to determine the number and nature of the factors concerned, and in illustration of this we may take another example from rabbits. The Himalayan rabbit is a well-known breed. In appearance it is a white rabbit with pink eyes, but the ears, paws, and nose are black (Pl. I., 2). The Dutch rabbit is another well-known breed. Generally speaking, the anterior portion of the body is white, and the posterior part coloured. Anteriorly, however, the eyes are surrounded by coloured patches extending up to the ears, which are entirely coloured. At the same time the hind paws are white (cf. Pl. I., 1). Dutch rabbits exist in many varieties of colour, though in each one of these the distribution of colour and white shows the same relations. In the experiments about to be described a yellow Dutch rabbit was crossed with a Himalaya. The result was a reversion to the wild agouti colour (Pl. I., 3). Some of the  $F_1$  individuals showed white patches, while others were self-coloured. On breeding from the  $F_1$  animals a series of coloured forms resulted in  $F_2$ . These were agoutis, blacks, yellows, and sooty yellows, the so-called tortoise-shells of the fancy (Pl. I., 4-7). In addition to these appeared Himalayans with either black points or with lighter brownish ones, and the proportions in which they came showed the Himalayan character to be a simple recessive. A certain number of the coloured forms exhibited the Dutch marking to a

greater or less extent, but as its inheritance in this set of experiments is complicated and has not yet been worked out, we may for the present neglect it and confine our attention to the coloured types and to the Himalayans. The proportion in which the four coloured types appeared in  $F_2$  was very nearly 9 agoutis, 3 blacks, 3 yellows, and 1 tortoiseshell. Evidently we are here dealing with two factors: (1) the grey factor ( $G$ ), which modifies black into agouti, or tortoiseshell into yellow; and (2) an intensifying factor ( $I$ ), which intensifies yellow into agouti and

tortoiseshell into black. It may be mentioned here that other experiments confirmed the view that the yellow rabbit is a dilute agouti, and the tortoiseshell a dilute black. The Himalayan pattern behaves as a recessive to self-colour. It is a self-coloured black rabbit lacking a factor that allows the colour to develop except in the points. That factor we may denote by  $X$ , and as far as it is concerned the Himalayan is constitutionally  $xx$ . The Himalayan contains the intensifying factor, for such pigment as it possesses in the points is full coloured. At the same time it is black, *i.e.* lacking in the factor  $G$ . With regard to these three factors, therefore, the constitution of the Himalayan is  $ggIIxx$ . The last char-

acter which we have to consider in this cross is the Dutch character. This was found by Hurst to behave as a recessive to self-colour ( $S$ ), and for our present purpose we will regard it as differing from a self-coloured rabbit in the lack of this factor.<sup>1</sup> The Himalayan is really a self-coloured animal, which, however, is unable to show itself as a full black owing to its not possessing the factor  $X$ . The results of breeding experiments then suggest that we may denote the Himalayan by the formula  $ggIixxSS$  and the yellow Dutch by  $GGiiXXss$ . Each lacks two of the factors upon the full complement of which the agouti colour depends. By crossing them the complete series  $GIXS$  is brought into the same zygote, and the result is a reversion to the colour of the wild rabbit.

Most of the instances of reversion yet worked out are those in which colour characters are concerned. The sweet-pea, however, supplies us with a good example of reversion in structural characters. A dwarf variety known as the "Cupid" has been extensively grown for some years. In these little plants the internodes are very short and the stems are few in number, and attain to a length of only 9-10 inches. In course of growth they diverge from one another, and come to lie prostrate on the ground (Pl. II., 2). Curiously enough, although the whole plant is dwarfed in other respects, this does not seem to affect the size of the flower, which is that of a normal sweet-pea. Another though less-known variety is the "Bush" sweet-pea. Its name is derived from

<sup>1</sup> Hurst's original cross was between a Belgian hare and an albino Angora which turned out to be a masked Dutch.

its habit of growth. The numerous stems do not diverge from one another, but all grow up side by side giving the plant the appearance of a compact bush (Pl. II., 1). Under ordinary conditions it attains a height of  $3\frac{1}{2}$ -4 feet. A number of crosses were made between the Bush and Cupid varieties, with the somewhat unexpected result that in every instance the  $F_1$  plants showed complete reversion to the size and habit of the ordinary tall sweet-pea (Pl. II., 3), which is the form of the wild plant as it occurs in Sicily to-day. The  $F_2$  generation from

these reversionary tall consisted of four different types, viz. tall, bushes, Cupids of the procumbent type like the original Cupid parent, and Cupids with the compact upright Bush habit (Pl. II., 4). These four types appeared in the ratio 9 : 3 : 3 : 1, and this, of course, provided the clue to the nature of the case. The characters concerned are (1) long internode of stem between the leaves which is dominant to short internode, and (2) the creeping procumbent habit which is dominant to the erect bush-like habit. Of these characters length of internode was carried by the Bush, and the procumbent habit by the original Cupid parent. The bringing of them together by the cross resulted in a pro-

# PLATE II.

1, Bush Sweet Pea;    2, Cupid Sweet Pea;    3,  $F_1$  reversionary Tall;  
 4, Erect Cupid Sweet Pea;    5, Purple Invincible;    6, Painted Lady;  
 7, Duke of Westminster (hooded standard).

cumbent plant with long internodes. This is the ordinary tall sweet-pea of the wild Sicilian type, reversion here, again, being due to the bringing together of two complementary factors which had somehow become separated in the course of evolution.

To this interpretation it may be objected that the ordinary sweet-pea is a plant of upright habit. This, however, is not true. It only appears so because the conventional way of growing it is to train it up sticks. In reality it is of procumbent habit, with divergent stems like the ordinary Cupid, a fact which can easily be observed by any one who will watch them grow without the artificial aid of prepared supports.

The cases of reversion with which we have so far dealt have been cases in which the reversion occurs as an immediate result of a cross, *i.e.* in the  $F_1$  generation. This is perhaps the commonest mode of reversion, but instances are known in which the reversion that occurs when two pure types are crossed does not appear until the  $F_2$  generation. Such a case we have already met with in the fowls' combs. It will be remembered that the cross between pure pea and pure rose gave walnut combs in  $F_1$ , while in the  $F_2$  generation a definite proportion, 1 in 16, of single combs appeared (cf. p. 31). Now the single comb is the form that is found in the wild jungle fowl, which is generally regarded as the ancestor of the domestic breeds. If this is so, we have a case of reversion in  $F_2$ ; and this in the *absence* of the two factors brought together by the rose-comb and pea-comb parents. Instead of the reversion being due to the

bringing together of two complementary factors, we must regard it here as due to the association of two complementary absences. To this question, however, we shall revert later in discussing the origin of domesticated varieties.

There is one other instance of reversion to which

we must allude. This is Darwin's famous case of the occasional appearance of pigeons reverting to the wild blue rock (*Columba livia*) when certain domesticated races are crossed together. As is well known, Darwin made use of this as an

argument for regarding all the domesticated varieties as having arisen from the same wild species. The original experiment is somewhat complicated, and is shown in the accompanying scheme. Essentially

<sup>1</sup> This is an almost white bird, the colour being confined to the tail and the characteristic spot on the head.

it lay in following the results flowing from crosses between blacks and whites. Experiments recently made by Staples-Browne have shown that this case of reversion also can be readily interpreted in Mendelian terms. In these experiments the cross was made between black barbs and white fantails. The  $F_1$  birds were all black with some white splashes, evidently due to a separate factor introduced by the fantail. On breeding these blacks together they gave an  $F_2$  generation, consisting of blacks (with or without white splashes), blues (with or without white splashes), and whites in the ratio 9:3:4. The factors concerned are colour ( $C$ ), in the absence of which a bird is white, and

a black modifier ( $B$ ), in the absence of which a coloured bird is blue. The original black barb contained both of these factors, being in constitution  $CCBB$ . The fantail, however, contained neither, and was constitutionally  $cbb$ . The  $F_1$  birds produced by crossing were in constitution  $CcBb$ , and being heterozygous for two factors produced in equal numbers the four sorts of gametes  $CB$ ,  $Cb$ ,  $cB$ ,  $cb$ .

$CB$ $CB$ BLACK	$CB$ $Cb$ BLACK	$CB$ $cB$ BLACK	$CB$ $cb$ BLACK
$Cb$ $CB$ BLACK	$Cb$ $Cb$ Blue	$Cb$ $cB$ BLACK	$Cb$ $cb$ Blue
$cB$ $CB$ BLACK	$cB$ $Cb$ BLACK	$cB$ $cB$ WHITE	$cB$ $cb$ WHITE
$cb$ $CB$ BLACK	$cb$ $Cb$ Blue	$cb$ $cB$ WHITE	$cb$ $cb$ WHITE

FIG. 11.

Diagram to illustrate the appearance of the reversionary blue pigeon in  $F_2$  from the cross of black with white.

The results of two such series of gametes being brought together are shown in the usual way in Fig. 11. A blue is a bird containing the colour factor but lacking the black modifier, *i.e.* of the constitution *CCbb*, or *Ccbb*, and such birds as the figure shows appear in the  $F_2$  generation on the average three times out of sixteen. Reversion here comes about in  $F_2$ , when the redistribution of the factors leads to the formation of zygotes containing one of the two factors but not the other.

## CHAPTER VII

### DOMINANCE

IN the cases which we have hitherto considered the presence of a factor produces its full effect whether it is introduced by both of the gametes which go to form the zygote, or by one of them alone. The heterozygous tall pea or the heterozygous rose-combed fowl cannot be distinguished from the homozygous form by mere inspection, however close. Breeding tests alone can decide which is the heterozygous and which the homozygous form. Though this is true for the majority of characters yet investigated, there are cases known in which the heterozygous form differs in appearance from either parent. Among plants such a case has been met with in the primula. The ordinary Chinese primula (*P. sinensis*) (Fig. 12) has large rather wavy petals much crenated at the edges. In the Star Primula (*P. stellata*) the flowers are much smaller, while the petals are flat and present only a terminal notch instead of the numerous crenations of *P. sinensis*. The heterozygote produced by crossing these forms is intermediate in size and appearance. When self-fertilised such plants behave in simple Mendelian

fashion, giving a generation consisting of *sinensis*, intermediates, and *stellata* in the ratio 1 : 2 : 1. Subsequent breeding from these plants showed that both the *sinensis* and *stellata* which appeared in the  $F_2$  generation bred true, while the intermediates

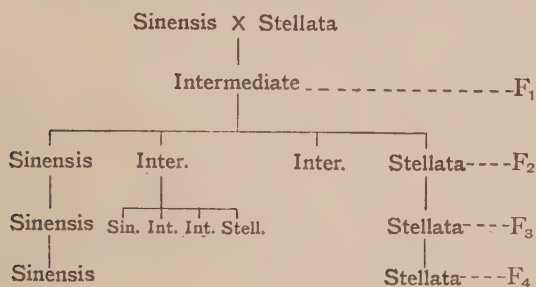

FIG. 12.

Primula flowers to illustrate the intermediate nature of the  $F_1$  flower when *sinensis* is crossed with *stellata*.

always gave all three forms again in the same proportion. But though there is no dominance of the character of either parent in such a case as this, the Mendelian principle of segregation could hardly have a better illustration.

Among birds a case of similar nature is that of the Blue Andalusian fowl. Fanciers have long

recognised the difficulty of getting this variety to breed true. Of a slaty blue colour itself with darker hackles and with black lacing on the

feathers of the breast, it always throws "wasters" of two kinds, viz. blacks, and whites splashed with blue. Careful breeding from the blues shows that the three sorts are always produced in the same

definite proportions, viz. one black, two blues, one splashed white. This at once suggests that the black and the splashed white are the two homozygous forms, and that the blues are heterozygous, *i.e.*

producing equal numbers of "black" and "white splashed" gametes. The view was tested by breeding the "wasters" together—black with black, and splashed white with splashed white—and it was found that each bred true to its respective type. But when the black and the splashed white were crossed they gave, as was expected, nothing but blues. In other words, we have the seeming paradox of the black and the splashed white producing twice as many blues as do the blues when bred together. The black and the splashed white "wasters" are in reality the pure breeds, while the "pure" Blue Andalusian is a mongrel which no amount of selection will ever be able to fix.

In such cases as this it is obvious that we cannot speak of dominance. And with the disappearance of this phenomenon we lose one criterion for determining which of the two parent forms possesses the additional factor. Are we, for example, to regard the black Andalusian as a splashed white to which has been added a double dose of a colour-intensifying factor, or are we to consider the white splashed bird as a black which is unable to show its true pigmentation owing to the possession of some inhibiting factor which prevents the manifestation of the black? Either interpretation fits the facts equally well, and until further experiments have been devised and carried out it is not possible to decide which is the correct view.

Besides these comparatively rare cases where the heterozygote cannot be said to bear a closer resemblance to one parent more than to the other, there are cases in which it is often possible to draw

a visible distinction between the heterozygote and the pure dominant. There are certain white breeds of poultry, notably the White Leghorn, in which the white behaves as a dominant to colour. But the heterozygous whites made by crossing the dominant white birds with a pure coloured form (such as the Brown Leghorn) almost invariably show a few coloured feathers or "ticks" in their plumage. The dominance of white is not quite complete, and renders it possible to distinguish the pure from the impure dominant without recourse to breeding experiments.

This case of the dominant white fowl opens up another interesting problem in connection with dominance. By accepting the Presence and Absence hypothesis we are committed to the view that the dominant form possesses an extra factor as compared with the recessive. The natural way of looking at this case of the fowl is to regard white as the absence of colour. But were this so, colour should be dominant to white, which is not the case. We are therefore forced to suppose that the absence of colour in this instance is due to the presence of a factor whose property is to inhibit the production of colour in what would otherwise be a pure coloured bird. On this view the dominant white fowl is a coloured bird plus a factor which inhibits the development of the colour. The view can be put to the test of experiment. We have already seen that there are other white fowls in which white is recessive to colour, and that the whiteness of such birds is due to the fact that they lack a factor for the development of colour. If we denote this factor by  $C$  and our postulated inhibitor factor in the dominant

white bird by  $I$ , then we must write the constitution of the recessive white as  $ccii$ , and the dominant white as  $CCII$ . We may now work out the results we ought to obtain when a cross is made between these two pure white breeds. The constitution of the  $F_1$  bird must be  $CcIi$ . Such birds being heterozygous for the inhibitor factor, should be whites showing some coloured "ticks." Being heterozygous for both of the two factors  $C$  and  $I$ , they will produce in equal numbers the four different sorts of gametes  $CI$ ,  $Ci$ ,  $cI$ ,  $ci$ . The result of bringing two such similar series of gametes together is shown in Fig. 13. Out of the sixteen squares, twelve contain  $I$ ; these will be white birds either with or without a few coloured ticks.

$CI$ $CI$	$CI$ $Ci$	$CI$ $cI$	$CI$ $ci$
$Ci$ $CI$	$Ci$ $Ci$	$Ci$ $cI$	$Ci$ $ci$
$cI$ $CI$	$cI$ $Ci$	$cI$ $cI$	$cI$ $ci$
$ci$ $CI$	$ci$ $Ci$	$ci$ $cI$	$ci$ $ci$

FIG. 13.

Diagram to illustrate the nature of the  $F_2$  generation from the cross between dominant white and recessive white fowls.

Three contain  $C$  but not  $I$ ; these must be coloured birds. One contains neither  $C$  nor  $I$ ; this must be a white. From such a mating we ought, therefore, to obtain both white and coloured birds in the ratio 13:3. The results thus theoretically deduced were found to accord with the

actual facts of experiment. The  $F_1$  birds were all "ticked" whites, and in the  $F_2$  generation came white

and coloured birds in the expected ratio. There seems, therefore, little reason to doubt that the dominant white is a coloured bird in which the absence of colour is due to the action of a colour-inhibiting

FIG. 14.

Ears of beardless and bearded wheat. The beardless condition is dominant to the bearded.

factor, though as to the nature of that factor we can at present make no surmise.

Experiments with plants may often, as we have already seen, throw light upon the heredity of animals, and the converse is equally true. The inhibitor in poultry has its counterpart in wheat. Some early

work of Biffen showed that the beardless behaved as a simple dominant to the bearded condition with its long awns (Fig. 14). The beard is obviously the additional character, and on the Presence and Absence theory we should have expected it to be dominant. The fact that it was not so suggested that the beardless wheats with which Biffen worked, contained an inhibitor suppressing the growth of the beard. This suggestion has recently been confirmed by Howard, who has been able to demonstrate two forms of beardless wheat, one of which is dominant and the other recessive to the bearded form. When these two kinds of beardless wheats are crossed, they produce a certain proportion of bearded offspring in  $F_2$ , just as the two kinds of white poultry produce a certain number of coloured birds. It is not unlikely that as time goes on we shall find many more such cases of the action of inhibitor factors, and we must be prepared to find that the same visible effect may be produced either by the addition or by the omission of a factor. The dominant and recessive white poultry are indistinguishable in appearance. Yet the one contains a factor more and the other a factor less than the coloured bird.

A phenomenon sometimes termed irregularity of dominance has been investigated in a few cases. In certain breeds of poultry such as Dorkings there occurs an extra toe directed backwards like the hallux (cf. Fig. 15). In some families this character behaves as an ordinary dominant to the normal, giving the expected 3:1 ratio in  $F_2$ . But in other families similarly bred the proportions of birds with and without the extra toe appear to be unusual. It has

been shown that in such a family some of the birds without the extra toe may nevertheless transmit the peculiarity when mated with birds belonging to strains in which the extra toe never occurs. Though the external appearance of the bird generally affords some indication of the nature of the gametes which it is carrying, this is not always the case. Nevertheless we have reason to suppose that the character segregates in the gametes, though the nature of these cannot

FIG. 15.

Fowls' feet. On the right a normal, and on the left one with an extra toe.

always be decided from the appearance of the bird which bears them.

There are cases in which an apparent irregularity of dominance has been shown to depend upon another character, as in the experiments with sheep carried out by Professor Wood. In these experiments two breeds were crossed, of which one, the Dorset, is horned in both sexes, while the other, the Suffolk, is without horns in either sex (cf. Plate III.). Whichever way the cross was made the resulting  $F_1$

generation was similar; the rams were horned, and the ewes were hornless. In the  $F_2$  generation raised from these  $F_1$  animals both horned and hornless types appeared in both sexes but in very different proportions. While the horned rams were about three times as numerous as the hornless, this relation was reversed among the females, in which the horned formed only about one-quarter of the total. The

FIG. 16.

Scheme to illustrate the inheritance of horns in sheep. Heterozygous males shown dark with a white spot, heterozygous females light with a dark spot in the centre.

simplest explanation of this interesting case is to suppose that the dominance of the horned character depends upon the sex of the animal—that it is dominant in the male, but recessive in the female. A pretty experiment was devised for putting this view to the test. If it is true, equal numbers of gametes with and without the horned factor must be produced by the  $F_1$  ewes, while the factor should be lacking in all the gametes of the hornless  $F_2$  rams. A hornless ram, therefore, put to a flock of  $F_1$  ewes should give rise to equal numbers of zygotes which are heterozygous

TYPES APPEARING IN  $F_2$

for the horned character, and of zygotes in which it is completely absent. And since the heterozygous males are horned, while the heterozygous females are hornless, we should expect from this mating equal numbers of horned and hornless rams, but only hornless ewes. The result of the experiment confirmed this expectation. Of the ram lambs 9 were horned and 8 were hornless, while all the 11 ewe lambs were completely destitute of horns.

## CHAPTER VIII

### WILD FORMS AND DOMESTIC VARIETIES

IN discussing the phenomena of reversion we have seen that in most cases such reversion occurs when the two varieties which are crossed each contain certain factors lacking in the other, of which the full complement is necessary for the production of the reversionary wild form. This at once suggests the idea that the various domestic forms of animals and plants have arisen by the omission from time to time of this factor or of that. In some cases we have clear evidence that this is the most natural interpretation of the relation between the cultivated and the wild forms. Probably the species in which it is most evident is the sweet-pea (*Lathyrus odoratus*). We have already seen reason to suppose that as regards certain structural features the Bush variety is a wild lacking the factor for the procumbent habit, that the Cupid is a wild without the factor for the long internode, and that the Bush Cupid is a wild minus both these factors. Nor is the evidence less clear for the many colour varieties. In illustration we may consider in more detail a case in which the cross between two whites

# PLATE IV.

1, 2, Emily Henderson; 3,  $F_1$  reversionary Purple; 4-10, Various  $F_2$  forms; 4, Purple; 5, Deep Purple; 6, Picotee; 7, Painted Lady; 8, Miss Hunt; 9, Tinged White; 10, White.

resulted in a complete reversion to the purple colour characteristic of the wild Sicilian form (Pl. IV.). In this particular instance subsequent breeding from the purples resulted in the production of six different colour forms in addition to whites. The proportion of the coloured forms to the whites was 9:7 (cf. p. 41), but it is with the relation of the six coloured forms that we are concerned here. Of these six forms, three were purples and three were reds. The three purple forms were (1) the wild bicolor purple with blue wings known in cultivation as the Purple Invincible (Pl. IV., 4); (2) a deep purple with purple wings (Pl. IV., 5); and (3) a very dilute purple known as the Picotee (Pl. IV., 6). Corresponding to these three purple forms were three reds: (1) a bicolor red known as Painted Lady (Pl. IV., 7); (2) a deep red with red wings known as Miss Hunt (Pl. IV., 8); and (3) a very pale red which we have termed Tinged White<sup>1</sup> (Pl. IV., 9). In the F<sub>2</sub> generation the total number of purples bore to the total number of reds the ratio 3:1, and this ratio was maintained for each of the corresponding classes. Purple, therefore, is dominant to red, and each of the three classes of red differs from its corresponding purple in not possessing the blue factor (*B*) which turns it into purple. Again, the proportion in which the three classes of purples appeared was 9 bicolors, 3 deep purples, 4 picotees. We are, therefore, concerned here with the operation of two factors: (1) a light wing factor, which renders the bicolor

<sup>1</sup> The reader who searches florists' catalogues for these varieties will probably experience disappointment. The sweet-pea has been much "improved" in the past few years, and it is unlikely that the modern seedsman would list such unfashionable forms.

dominant to the dark winged form ; and (2) a factor for intense colour, which occurs in the bicolor and in the deep purple, but is lacking in the dilute picotee. And here it should be mentioned that these conclusions rest upon an exhaustive set of experiments involving the breeding of many thousands of plants. In this cross, therefore, we are concerned with the presence or absence of five factors, which we may denote as follows :—

- A colour base, *R*.
- A colour developer, *C*.
- A purple factor, *B*.
- A light wing factor, *L*.
- A factor for intense colour, *I*.

On this notation our six coloured forms are :—

- (1) Purple bicolor . . . . *CRBLI*.<sup>1</sup>
- (2) Deep purple . . . . *CRbII*.
- (3) Picotee . . . . *CRBLi* or *CRBii*.
- (4) Red bicolor ( = Painted Lady ) *CRbLI*.
- (5) Deep red ( = Miss Hunt ) . *CRbII*.
- (6) Tinged white . . . . *CRbLi* or *CRbli*.

It will be noticed in this series that the various coloured forms can be expressed by the omission of one or more factors from the purple bicolor of the wild type. With the complete omission of each factor a new colour type results, and it is difficult to resist the inference that the various cultivated forms of the sweet-pea have arisen from the wild by some process of this kind. Such a view tallies with what we know of the behaviour of the wild

<sup>1</sup> It is to be understood that wherever a given factor is present the plant may be homozygous or heterozygous for it without alteration in its colour.

form when crossed by any of the garden varieties. Wherever such crossing has been made the form of the hybrid has been that of the wild, thus supporting the view that the wild contains a complete set of all the differentiating factors which are to be found in the sweet-pea.

Moreover, this view is in harmony with such historical evidence as is to be gleaned from botanical literature, and from old seedsmen's catalogues. The wild sweet-pea first reached this country in 1699, having been sent from Sicily by the monk Franciscus Cupani as a present to a certain Dr. Uvedale in the county of Middlesex. Somewhat later we hear of two new varieties, the red bicolor, or Painted Lady, and the white, each of which may be regarded as having "sported" from the wild purple by the omission of the purple factor, or of one of the two colour factors. In 1793 we find a seedsman offering also what he called black and scarlet varieties. It is probable that these were our deep purple and Miss Hunt varieties, and that somewhere about this time the factor for the light wing (*L*) was dropped out in certain plants. In 1860 we have evidence that the pale purple or Picotée, and with it doubtless the Tinged White, had come into existence. This time it was the factor for intense colour which had dropped out. And so the story goes on until the present day, and it is now possible to express by the same simple method the relation of the modern shades, of purples and reds, of blues and pinks, of hooded and wavy standards, to one another and to the original wild form. The constitution of many of these has now been worked out, and to-day it

would be a simple though perhaps tedious task to denote all the different varieties by a series of letters indicating the factors which they contain, instead of by the present system of calling them after kings and queens, and famous generals, and ladies more or less well known.

From what we know of the history of the various strains of sweet-peas one thing stands out clearly. The new character does not arise from a pre-existing variety by any process of gradual selection, conscious or otherwise. It turns up suddenly complete in itself, and thereafter it can be associated by crossing with other existing characters to produce a gamut of new varieties. If, for example, the character of hooding in the standard (cf. Pl. II, 7) suddenly turned up in such a family as that shown on Plate IV., we should be able to get a hooded form corresponding to each of the forms with the erect standard; in other words, the arrival of the new form would give us the possibility of fourteen varieties instead of seven. As we know, the hooded character already exists. It is recessive to the erect standard, and we have reason to suppose that it arose as a sudden sport by the omission of the factor in whose presence the standard assumes the erect shape characteristic of the wild flower. It is largely by keeping his eyes open and seizing upon such sports for crossing purposes that the horticulturist "improves" the plants with which he deals. How these sports or **mutations** come about we can at present but surmise. We are once more up against the old problem discussed by Plutarch centuries ago, whether the owl came first or the

egg? There are many who plump for the egg; who see in the new form the manifestation of a new kind of gamete in which, through some disturbance in the normal process of division, a factor has been omitted, or perhaps added. At some stage or other, the normal equal distribution of the various factors has been upset, whereby some of the gametes receive a factor less or a factor more than the others. From the union of two such gametes, provided they are still capable of fertilisation, comes the zygote which in course of growth develops the new character. It may be that in some cases this is the sequence of events, and that the egg precedes the owl. But there are others which suggest that the owl came first.

One of the best pedigree of all sports is the "cretin" sweet-pea, a monstrous form so called from its fancied resemblance to a gaping mouth with a protruding tongue (cf. Fig. 17). It appeared suddenly in a large family belonging to a strain in which thousands of normal individuals had been accurately recorded over a period of several years. From its first appearance it behaved as a simple recessive to the normal form, and has continued to do so ever since. It had more than 200 normal sisters, of which none that were tested threw any cretins. If the parent plant had been producing an appreciable number of "cretin" gametes, we should have expected an appreciable proportion of the cretin's sisters to have thrown cretins. And if the parent plant had been producing very few such gametes, it is almost incredible that the only cretin egg to produce a plant should have been fertilised by a cretin pollen

grain, when these were so vastly outnumbered by normal ones. The evidence in this case suggests that two normal gametes met, that subsequently a radical change occurred in the young zygote, whereby the normal factor was somehow obliterated.

The exact point of origin of few, if any, mutations

FIG. 17.

The "cretin" sweet-pea.

is so well established as that of the cretin. Nevertheless enough is known to show that they frequently occur in the same way—as rare and isolated instances in a strain of normals, and behaving as simple recessives to those normals. Evidently we have not yet found the solution to Plutarch's problem.

In respect of the evolution of its now multitudinous varieties, the story of the sweet-pea is clear and straightforward. These have all arisen from the wild by a process of continuous loss. Everything was there in the beginning, and as the wild plant parted with factor after factor there came into being the long series of derived forms. Exquisite as are the results of civilisation, it is by the degradation of the wild that they have been brought about. How far are we justified in regarding this as a picture of the manner in which evolution works?

There are certainly other species in which we must suppose that this is the way that the various domesticated forms have arisen. Such, for example, is the case in the rabbit, where most of the colour varieties are recessive to the wild agouti form. Such also is the case in the rat, where the black and albino varieties and the various pattern forms are also recessive to the wild agouti type. And with the exceptions of a pied form and a certain yellow variety to which we shall refer later, such is also the case with the many fancy varieties of mice.

Nevertheless there are other cases in which we must suppose evolution to have proceeded by the interpolation of characters. In discussing reversion on crossing, we have already seen that this may not occur until the  $F_2$  generation, as, for example, in the instance of the fowls' combs (cp. p. 59). The reversion to the single comb occurred as the result of the removal of the two factors for rose and pea. These two domesticated varieties must be regarded as each possessing an additional factor in comparison with the wild single-combed bird. During the evolution

of the fowl, these two factors must be conceived of as having been interpolated in some way. And the same holds good for the inhibitory factor on which, as we have seen, the dominant white character of certain poultry depends. In pigeons, too, if we regard the blue rock as the ancestor of the domesticated breeds, we must suppose that an additional melanic factor has arisen at some stage. For we have already seen that black is dominant to blue, and the characters of  $F_1$ , together with the greater number of blacks than blues in  $F_2$ , negatives the possibility that we are here dealing with an inhibitory factor. The hornless or polled condition of cattle, again, is dominant to the horned condition, and if, as seems reasonable, we regard the original ancestors of domestic cattle as having been horned, we have here again the interpolation of an inhibitory factor somewhere in the course of evolution.

On the whole, therefore, we must be prepared to admit that the evolution of domestic varieties may come about by a process of addition of factors in some cases and of subtraction in others. It may be that what we term additional factors fall into distinct categories from the rest. So far, experiment seems to show that they are either of the nature of melanic factors, or of inhibitory factors, or of reduplication factors as in the case of the fowls' combs. But while the data remain so scanty, speculation in these matters is too hazardous to be profitable.

## CHAPTER IX

### SEX

IN their simplest expression the phenomena exhibited by Mendelian characters are sharp and clean cut. Clean cut and sharp also are the phenomena of sex. It was natural, therefore, that a comparison should have been early instituted between these two sets of phenomena. As a general rule, the cross between a male and a female results in the production of the two sexes in approximately equal numbers. The cross between a heterozygous dominant and a recessive also leads to equal numbers of recessives and of heterozygous dominants. Is it not, therefore, possible that one of the sexes is heterozygous for a factor which is lacking in the other, and that the presence or absence of this factor determines the sex of the zygote? The results of some recent experiments would appear to justify this interpretation, at any rate in particular cases. An excellent illustration may be taken from poultry. Many breeds of fowls are to be found in gold and in silver varieties, the two birds differing essentially only in colour. The gold-laced Wyandotte has its counterpart in the silver-laced Wyandotte; the

gold-pencilled Hamburgh in the silver-pencilled Hamburgh; the gold Sebright bantam in the silver Sebright, and so for many other kinds. The gold and the silver forms each breed true to their own colour. But when they are crossed certain definite and remarkable phenomena make their appearance. If we mate a silver Sebright cock from a pure silver strain with a gold Sebright hen, the resulting chickens are all silvers (see Pl. V.). Silver is evidently dominant to gold, and this is confirmed when the silver  $F_1$  birds are mated together. The  $F_2$  generation consists of silvers and golds in the ratio 3 : 1. So far the case is simple. A remarkable feature, however, is brought out when we come to regard the  $F_2$  generation from the point of view of the distribution of the sexes. As is commonly the case, they are produced in approximately equal numbers. But all of the recessive golds of the  $F_2$  generation are females. Not a single gold cock has been known to have arisen from such a mating. Further analysis has shown that the  $F_2$  silvers are, as is to be expected, of two kinds, viz. those which are homozygous and those which are heterozygous for the silver factor. When crossed with the recessive gold some of the  $F_2$  silvers gave nothing but silvers, while others, the heterozygotes, give silvers and golds in equal numbers. Of the heterozygotes some are cocks and some are hens, but all the homozygotes are cocks. The general results of this experiment are shown graphically in Fig. 18. They are capable of a simple explanation if we make the following assumption :

- (1) Silver is dominant to gold. This is evident

PLATE V.

## Sebright Bantams

from the 3 : 1 ratio obtained in  $F_2$ , as well as from the fact that the  $F_1$  birds mated with golds give equal numbers of golds and silvers.

(2) Femaleness is dominant to maleness, the female being heterozygous for a factor,  $F_1$ , which is not present in the male. This assumption is in accordance with the fact that the sexes are produced in equal numbers. The female must be supposed to produce equal numbers of female-producing eggs containing  $F$ , and of male-producing eggs which do not contain the factor. Since the male does not carry  $F$ , this factor cannot occur in any spermatozoon. Every female, on this view, receives the factor for femaleness from her mother.

(3) The silver hen is always heterozygous for the silver factor,  $S$ , as well as for that for femaleness,  $F$ . Moreover, it must be supposed that when she forms eggs some form of repulsion occurs between the two factors, of such a kind that they will not enter into the same gamete. The eggs of such a bird must be supposed to be of two kinds and of two kinds only, viz.  $Fs$  and  $fS$ .

If we make these assumptions, the experimental facts are open to a simple explanation, as shown graphically on Plate V. The original silver male was homozygous for  $S$ . As he cannot contain  $F$

FIG. 18.

Scheme illustrating the cross between a silver cock and a gold hen. Black sex signs denote gold, and light ones denote silver birds. Light sex signs with a dot in the middle denote heterozygous silvers.

all of his sperms are of the constitution  $fS$ .<sup>1</sup> The gold hen produces two kinds of eggs. All are alike in lacking the factor for silver, but half of them contain  $F$  while the other half lack this factor. The former are, of course, the female-producing eggs, and the latter the male-producing ones. The  $F_1$  cocks, therefore, may be represented in constitution as  $ffSs$ , the  $F_1$  hens as  $FfSs$ . The sperms produced by such cocks are of two kinds, viz.  $fS$  and  $fs$ : the eggs produced by the  $F_1$  hens are on hypothesis also of two kinds, viz.  $Fs$  and  $fs$ . Each of these two kinds of eggs has an equal chance of being fertilised by either of the two classes of sperms. Consequently, as Plate V. shows, four classes of birds are produced in  $F_2$ . The peculiar relation between colour and sex is explained on our hypothesis by the fact that all of her male-producing eggs contain the silver factor, while none of her female-producing eggs contain it. Since all males must receive  $S$  from their mother, the  $F_2$  generation of this sex consists of homozygous and heterozygous silvers in equal numbers: since the female-producing eggs alone lack the factor for silver, all of the recessive golds in the  $F_2$  generation must be hens.

If the view just set out is a true one, it follows that no silver hen can be homozygous for  $S$ . In strains of silvers which breed true the hens are always heterozygous for  $S$ . With regard to the factor for silver the type of mating in such a strain is always that of a homozygous dominant, the cock,

<sup>1</sup> On Plate V. the male-bearing eggs and sperms are marked by a capital  $M$  instead of by a small  $f$  as in the account given in the text.

with a heterozygous dominant, the hen. Consequently nothing but silvers appear in spite of the fact that the hens are invariably heterozygous. But if the gametes of the hen are always of the two types  $Fs$  and  $fS$ , if she always transmits femaleness and gold to her daughters, maleness and silver to her sons, we should expect this to be revealed at once when she is mated with a gold cock. Expectation is borne out by experience. Any silver hen, no matter how bred, when mated to a gold cock, produces only silver cocks and gold hens. She transmits her colour to her sons and her sex to her daughters. The results of this cross, together with the nature of the  $F_2$  generation produced by such  $F_1$  birds, are shown graphically on Plate V.

On our hypothesis the sperms of the  $F_1$  silver cock are of two sorts, silver and gold. Again the eggs of the gold  $F_1$  hen are of two sorts, male-bearing and female-bearing. Four kinds of birds should therefore result in  $F_2$ , viz. silver cocks and silver hens, gold cocks and gold hens. These four kinds should be produced in equal numbers, and the experience of the breeding-pen has fully ratified the demands of the hypothesis.

An essential feature of such cases as these lies in the different results obtained from reciprocal crosses between two strains breeding true to type. The Sebright bantams give an entirely different result according as the dominant silver factor is brought into the cross by the cock or by the hen, and wherever there is this marked difference in the reciprocal crosses the explanation will often prove to be the simple one outlined above. Several

other cases of the nature have already been worked out in poultry. The barred plumage of the Plymouth Rock is such a one. The barred character is dominant to full black, but a barred hen is always heterozygous for the barred factor. Mated with a black cock she always gives barred cocks and black hens. The cock in a pure breeding strain of Plymouth Rocks is homozygous for the barring factor. As a matter of fact, most strains will occasionally throw a few blacks, and in such cases the blacks are always pullets. This is because most strains are not pure bred in the sense that every cock is homozygous for the barring factor. Occasional cocks are heterozygous. When such cocks are mated with barred hens they produce barred and blacks in the ratio 3 : 1, just as the  $F_1$  silvers shown on Plate V. produce silvers and golds in the same ratio. And just as all the golds in the latter case are hens, so also are all the black hens in the former. The breeder of Plymouth Rocks who wishes to ensure that his strain should throw no blacks has only to make sure that the cocks from which he breeds are homozygous. This he can easily do by making a test mating with a black hen. If the cock throws no blacks in a dozen or so birds he is almost sure to be homozygous, and can subsequently be mated with barred hens with the certainty that the strain will thenceforth throw no blacks. For the occasional blacks depend upon the nature of the cock, the barred hens being always of the same constitution, no matter how they have been bred.

It is perhaps natural to regard the barred character of the plumage in the Plymouth Rock

•

PLATE VI.

as due to the presence of an inhibitory factor which prevents the full development of the black pigment (cf. p. 67). Inhibitory factors appear to play a considerable part in poultry, and another inhibitory factor offers an interesting example of the sex-limited type of inheritance which we have just discussed.

The Silky breed of fowls is characterised among other peculiarities by a remarkable abundance of melanic pigment. The skin is dull black, while the

comb and wattles are of a deep purple colour, contrasting sharply with the white plumage (Pl. VI., 3). Dissection shows that this black pigment is widely spread throughout the body, being especially marked in such membranes as the mesenteries, the periosteum, and the pia mater sur-

rounding the brain. It also occurs in the connective tissues among the muscles. In the Brown Leghorn, on the other hand, this pigment is not found. Reciprocal crosses between these two breeds gave a remarkable difference in result. A cross between the Silky hen and the Brown Leghorn cock produced  $F_1$  birds, in which both sexes exhibited only traces of the pigment. On casual observation they might have passed for unpigmented birds, for with the exception of an occasional fleck of pigment their skin, comb, and wattles were as clear as in the

FIG. 19.

Scheme illustrating the result of crossing a Silky hen with a Brown Leghorn cock. Black sex signs denote deeply pigmented birds, and light sex signs those without pigmentation. The light signs with a black dot in the centre denote birds with a small amount of pigment.

Brown Leghorn (Pl. VI., 1 and 4). Dissection revealed the presence of a slight amount of internal pigment. Such birds bred together gave some offspring with the full pigmentation of the Silky, some without any pigment, and others showing different degrees of pigment. None of the  $F_2$  male birds, however, showed the full deep pigmentation of the Silky.

FIG. 20.

Scheme illustrating the result of crossing a Brown Leghorn hen with a Silky cock (cf. Fig. 19).

nearly as deeply pigmented as the pure Silky (Pl. VI., 2). The male Silky transmitted the pigmentation, but only to his daughters. Such birds bred together gave an  $F_2$  generation containing chicks with the full deep pigment, chicks without pigment, and chicks with various grades of pigmentation, all the different kinds in both sexes.

In analysing this complicated case many other different crosses were made, but for the present it will be sufficient to mention but one of these, viz. that between the  $F_1$  birds and the pure Brown Leghorn. The cross between the  $F_1$  hen and the Brown Leghorn cock produced only birds with a

slight amount of pigment and birds without pigment. And this was true for both the deeply pigmented and the slightly pigmented types of  $F_1$  hen. But when the  $F_1$  cock was mated to a Brown Leghorn hen, a definite proportion of the chicks, one in eight, were deeply pigmented, and *these deeply pigmented birds were always females* (cf. Fig. 21). And in this respect all the  $F_1$  males behaved alike, whether they were from the Silky hen or from the Silky cock. We have, therefore, the paradox that the  $F_1$

FIG. 21.

Scheme to illustrate the result of crossing  $F_1$  birds (e.g. Brown Leghorn  $\times$  Silky) with the pure Brown Leghorn.

hen, though herself deeply pigmented, cannot transmit this condition to any of her offspring when she is mated to the unpigmented Brown Leghorn, but that, when similarly mated, the  $F_1$  cock can transmit this pigmented condition to a quarter of his female offspring, though he himself is almost devoid of pigment.

Now all these apparently complicated results, as well as many others to which we have not alluded, can be expressed by the following simple scheme. There are three factors affecting pigment, viz. (1) a pigmentation factor ( $P$ ); (2) a factor which inhibits the production of pigment ( $I$ ); and (3) a

factor for femaleness ( $F$ ), for which the female birds are heterozygous, but which is not present in the males. Further, we make the assumptions ( $a$ ) that there is repulsion between  $F$  and  $I$  in the female zygote ( $FfIi$ ), and ( $b$ ) that the male Brown Leghorn is homozygous for the inhibitor factor ( $I$ ), but that the hen Brown Leghorn is always heterozygous for this factor just in the same way as the female of the currant moth is always heterozygous for the *grossulariata* factor. We may now proceed to show how this explanation fits the experimental facts which we have given.

The Silky is pure for the pigmentation factor, but does not contain the inhibitor factor. The

FIG. 22.

Scheme to illustrate the nature of the  $F_1$  generation from the Silky hen and Brown Leghorn cock (cf. Fig. 19).

for both  $P$  and  $I$ . In such birds the pigment is almost but not completely suppressed, and as both sexes are of the same constitution with regard to these two factors they are both of similar appearance.

In the reciprocal cross, on the other hand, we are mating a Silky male ( $ffPPii$ ) with a Brown Leghorn hen which on our assumption is heterozygous for the

Brown Leghorn, on the other hand, contains the inhibitor factor, but not the pigmentation factor. In crossing a Silky hen with a Brown Leghorn cock we are mating two birds of the constitution  $FfPPii$  and  $ffppII$ , and all the  $F_1$  birds are consequently heterozygous

inhibitor factor (*I*), and in constitution therefore is *FfppIi*. Owing to the repulsion between *F* and *I* the gametes produced by such a bird are *Fpi* and *fpI* in equal numbers. All the gametes produced by the Silky cock are *fPi*. Hence the constitution of the  $F_1$  male birds produced by this cross is *ffPpIi* as before, but the female birds must be all of the constitution *FfPpii*. The Silky cock transmits the fully pigmented condition to his daughters, because the gametes of the Brown Leghorn hen which contain the factor for femaleness do not contain the inhibitory factor owing to the repulsion between these factors. The nature of the  $F_2$  generation in each case is in harmony with the above scheme. As, however, it serves to illustrate certain points in connection with intermediate forms we shall postpone further

consideration of it till we discuss these matters, and for the present shall limit ourselves to the explanation of the different behaviour of the  $F_1$  males and females when crossed with the Brown Leghorn. And, first, the cross of Brown Leghorn female by  $F_1$  male. The Brown Leghorn hen is on our hypothesis *FfppIi*, and produces gametes *Fpi* and *fpI*. The  $F_1$  cock is on our hypothesis *ffPpIi*, and produces in equal numbers the four kinds of gametes *fPI*, *fPi*, *fpI*, *fpi*. The result of the meeting of

FIG. 23.

Scheme to illustrate the nature of the  $F_1$  generation from the Brown Leghorn hen and Silky cock (cf. Fig. 20).

these two series of gametes is given in Fig. 24. Of the eight different kinds of zygote formed only one contains  $P$  in the absence of  $I$ , and this is a female. The result, as we have already seen, is in accordance with the experimental facts.

On the other hand, the Brown Leghorn cock is on our hypothesis  $ffppII$ . All his gametes consequently contain the inhibitor factor, and when he

Fpi fPI ♀	Fpi fPi ♀	Fpi fpI ♀	Fpi fpi ♀
fpI fPI ♂	fpI fPi ♂	fpI fpI ♂	fpI fpi ♂

FIG. 24.

is mated with an  $F_1$  hen all the zygotes produced must contain  $I$ . None of his offspring, therefore, can be fully pigmented, for this condition only occurs in the absence of the in-

hibitor factor among zygotes which are either homozygous or heterozygous for  $P$ .

The interpretation of this case turns upon the constitution of the Brown Leghorn hen, upon her heterozygous condition with regard to the two factors  $F$  and  $I$ , and upon the repulsion that occurs between them when the gametes are formed. Through an independent set of experiments this view of the nature of the Brown Leghorn hen has been confirmed in an interesting way. There are fowls which possess neither the factor for pigment nor the inhibitory factor, which are in constitution  $ppii$ . Such birds when crossed with the Silky give dark pigmented birds of both sexes in  $F_1$ , and the  $F_2$  genera-

tion consists of pigmented and unpigmented in the ratio 3:1. Now a cock of such a strain crossed with a Brown Leghorn hen should give only completely unpigmented birds. But if, as we have supposed, the Brown Leghorn hen is producing gametes *Fpi* and *fpI*, the male birds produced by such a cross should be heterozygous for *I*, i.e. in constitution *ffppIi*, while the hen birds, though identical in appearance so far as absence of pigmentation goes, should not contain this factor but should be constitutionally *Ffppii*. Crossed with the pure Silky, the  $F_1$  birds of opposite sexes should give an entirely different result. For while the hens should give only deeply pigmented birds of both sexes, the cocks should give equal numbers of deeply pigmented and slightly pigmented birds (cf. Fig. 25). These were the results which the experiment actually gave, thus affording strong confirmation of the view which we have been led to take of the Brown Leghorn hen.

Essentially the Brown Leghorn case is that of the Sebrights and the Plymouth Rocks. It differs in that the factor which repels femaleness produces no visible effect, and its presence or absence can only be determined by the introduction of a third factor, that for pigmentation.

Sex-limited inheritance of the type we have been discussing has been demonstrated in other birds besides poultry. There is a white variety of the ring-dove which is recessive to the well-known fawn type. Fawn hens are always heterozygous, and when crossed with white cocks give only fawn cocks and white hens. In canaries, again, there are ruby-

eyed cinnamon forms corresponding to the various green and yellow varieties. Cinnamon is recessive and exhibits the same peculiar heredity. A point of interest in connection with the Silky and Canary cases is that in the course of the experimental work occasional exceptions have been recorded to the expectation demanded by the hypothesis. It is

FIG. 25.

Scheme to illustrate the heterozygous nature of the pure Brown Leghorn hen.  
For explanation see text.

possible that in the heterozygous hen the character factor and the sex factor do not always repel one another, but until more data are forthcoming the nature of these rare exceptions must remain undecided.

Apart from birds, there is one other form in which sex-limited inheritance of this particular type has been recorded. In the common currant moth (*Abraxas grossulariata*) a paler variety (*lacticolor*) is known to

occur (Fig. 26). This *lacticolor* variety is recessive to the normal form, and the work of Doncaster and Raynor has shown that it conforms to the type of sex-limited inheritance characteristic of birds. In connection with the currant moth there is a

FIG. 26.

*Abraxas grossulariata*, the common currant moth, and (on the right) its paler *lacticolor* variety.

further point of interest. *Lacticolor* occurs wild as a rare variety, but in Great Britain it has never been recorded except in the south. Nevertheless *grossulariata* females from Scotland, when paired with *lacticolor* males, give only *grossulariata* males and *lacticolor* females. Even where *lacticolor* has never been found wild, *grossulariata* females are nevertheless heterozygous.

## CHAPTER X

### SEX (*continued*)

THE facts with which we dealt in the last chapter are all in accordance with the hypothesis that the female is heterozygous for a given sex factor which is lacking in the male. The peculiar phenomenon of sex-limited heredity enables us to decide that in birds and moths the male is the homozygous and the female the heterozygous sex. It is a very curious fact that in certain other groups of animals this position is apparently reversed, the male being the heterozygous and the female the homozygous sex. This was first discovered by Morgan in one of the earliest of his remarkable series of experiments with the little pomace fly (*Drosophila ampelophila*), about which we shall have more to say later on. The wild *Drosophila* has a red eye. In certain of Morgan's cultures a few white-eyed males appeared. These were mated with normal red-eyed females, and gave only red-eyed offspring. In the  $F_2$  generation reds and whites were produced approximately in the ratio 3 : 1, but all of the whites were males. Further breeding tests showed that all of the red-eyed males were heterozygous, while of the

females about half were heterozygous and the other half were homozygous. A comparison of Fig. 27 with Fig. 18 on p. 85 makes it clear that the case of *Drosophila* is closely comparable with that of the Sebright bantams, except that the sexes, in respect of the factor showing sex-limited inheritance, are apparently reversed. Whereas in fowls it is the female which must be supposed to be heterozygous both in sex and in the sex-limited factor, in *Drosophila* it is the male. This view is confirmed by the results of the reciprocal cross, viz. red-eyed male  $\times$  white-eyed female. In order to make this cross it was first necessary to obtain the white-eyed female. This was done by mating the  $F_1$  female with a white-eyed male. Such a cross is comparable to that between a heterozygous silver

FIG. 27.

Scheme illustrating the cross between a white-eyed male *Drosophila* and a red-eyed female. Black sex signs denote white eye, and light ones denote red eye. Light sex signs with a dot in the middle denote heterozygous flies.

cock and a gold hen. Just as in the Sebrights this mating produces equal numbers of golds and silvers in both sexes, so in *Drosophila* it gave in both sexes equal numbers of red- and of white-eyed flies. Having obtained the white-eyed female it was possible to make the reciprocal cross. It resulted in offspring of two kinds only, viz. red-eyed females and white-eyed males. As in the Sebright, the sons take after the mother and the daughters after the father. The outstanding difference between the bantams and the flies is that in the former the

dominant character is carried by the mother, while in the latter it is carried by the father. To bring

FIG. 28.

Scheme illustrating the result of crossing a red-eyed male *Drosophila* with a white-eyed female. Sex signs as in Fig. 27.

the two cases into line it is necessary to suppose that the male *Drosophila* is always heterozygous both for the sex-factor and for the factor for red-eye. The hypothesis was confirmed by the results obtained when wild red-eyed males were mated with

white-eyed females. In all cases they gave red-eyed daughters and white-eyed sons only.

The brilliant researches of Morgan and his co-workers in America have carried the analysis of sex in *Drosophila* a stage further. They have been able to correlate these peculiar differences in sex-heredity with differences in the minute structure of the cells of which the bodies of the two sexes are composed. The microscopic cells of which the bodies of animals and plants are built up are composed of a semi-transparent jelly-like stuff called protoplasm. The precise nature of this differs in different cells: muscle cells differ from liver cells, and these again from brain cells. But all living cells agree in possessing a definite structure, the nucleus, which lies inside the cell, and apparently governs its activities. The nucleus, generally a minute round or oval body, possesses a definite structure of its own. Its most characteristic components are the chromosomes—

small elongated bodies which owe their name to the fact that they stain more deeply with various dyes than the rest of the cell protoplasm. At certain stages they stand out very clearly when appropriately stained, and it is then apparent that as regards number they are constant throughout the body cells of any given individual. They may vary greatly in size and shape, but these differences are remarkably definite, and a similar collection of chromosomes is to be found in the nucleus of every cell of an individual. Moreover, apart from the sex differences about to be mentioned, this resemblance in number and in shape persist throughout all the individuals of a given species. Distinct species, as a rule, exhibit a distinct and definite collection of chromosomes, so that an expert investigator can often, from the microscopic examination of a minute fragment of tissue, decide the species of animal from which it was taken. From the standpoint of this discussion there is one other feature to be mentioned. The number of the chromosomes in a cell of the body is generally an even one. This is because they normally exist in pairs. If, for example, the number is twelve, careful examination will show that there are six pairs. Each member of a given pair is visibly indistinguishable, though the members of different pairs may differ very greatly in size and shape. In such a case six different kinds of chromosomes can be distinguished. It is a peculiarity of the chromosomes that in the formation of the gametes their number is reduced by a peculiar and complex process to one half of the number found in the body cells. In our imaginary case, for instance, where the body

cells contain 12 chromosomes, the gametes will contain only 6. But the 6 chromosomes found in the gamete, whether egg or sperm, are representatives of each of the six pairs found in the body cells. When two gametes unite, each of the 6 chromosomes again finds its mate, and the condition of six pairs is again restored in the body cells of the new individual.

Some years ago it was discovered in America that in certain insects the number of chromosomes

FIG. 29.

Diagram illustrating the behaviour of the chromosomes in *Protenor*. The sex chromosomes are represented as unshaded. The remaining six pairs actually differ somewhat in size, but this is not indicated in the diagram.

differs in the two sexes. In the bug *Protenor*, for instance, there are 14 in the female, but only 13 in the male. The odd number in the male is due to the fact that one of the chromosomes is impaired. The female contains 7 pairs; the male 6 pairs and an odd one. The odd chromosome in the latter sex corresponds to a definite pair in the female. When the female forms gametes the number of chromosomes is halved, and every egg comes to contain a

representative of each of the 7 pairs, 14 chromosomes in all. But when the male forms gametes the odd chromosome does not divide. It passes over entire to one of the sperms, the other lacking it altogether. Consequently, two classes of sperms are found in equal number, viz. those possessing 7 and those having only 6 chromosomes. When a sperm containing 7 chromosomes fertilises an egg the complete quota of pairs is established, and the resulting individual is a female. But when an egg is fertilised by a sperm containing only 6 chromosomes, the individual that results contains but 6 pairs and an odd one, 13 chromosomes in all, and is a male. In such cases the sex of the individual is evidently determined by the presence of both members, or of only one, of this particular pair of chromosomes. For reasons, however, which may now be given, it is customary to speak of them as the *X* chromosomes. In the case of *Protenor* the *X* chromosome has no pair in the male. But in certain other species it has a pair, but a pair which differs in size and shape from itself. Generally the pair to the *X* chromosome in the male is smaller than the *X* chromosome itself, and can be readily distinguished from it. When present it is termed the *Y* chromosome. In such cases the constitution of the female is *XX* and all of her eggs contain an *X* chromosome. The male is *XY* in constitution, and half of the sperms he produces contain an *X* chromosome, while the other half contain a *Y* chromosome. Half of the offspring are *XX*, viz. females; the other half *XY*, males.

In *Drosophila ampelophila*, the species of pomace fly with which Morgan and his co-workers have

carried out their experiments, the number of chromosomes is 8. Of these, two pairs are alike and larger than the others (Fig. 30), one pair is very small, the remaining pair, the sex-chromosomes, being intermediate in size. In the female these take the form of 2  $X$  chromosomes, plain rod-like bodies. In the male there is an  $X$  chromosome, similar to those found in the female, and a  $Y$  chromosome of much the same size, but differing from the  $X$  chromosome

FIG. 30.

The chromosomes of the two sexes in *Drosophila* magnified about 5000 times. (After Bridges.) In the ♀ the two  $X$  are the lowest pair in the figure; in the ♂ their place is taken by a rod-shaped  $X$  chromosome and a hook-shaped  $Y$  chromosome.

in being bent into a hook at one end. All of the eggs therefore contain an  $X$  chromosome, but of the sperms half contain an  $X$  chromosome, and half contain a  $Y$  chromosome. When an egg is fertilised by a  $Y$  sperm it gives rise to a male. Now in order

to bring the chromosomes into relation with the facts of sex-limited inheritance, we have to make the assumption that the factors for sex-limited characters are carried by any  $X$  chromosome, but not by a  $Y$  chromosome, nor, of course, by any other of the pairs of chromosomes. In so far as this group of characters is concerned the  $Y$  chromosome behaves, as it were, like a dummy. Fig. 31 shows graphically how the results of the cross between the white-eyed male and the red-eyed female may be interpreted on these lines. Each of the  $X$  chromosomes of the female carries the factor for red, but this factor is lacking in the  $X$  chromosome of the

FIG. 31.

Illustrating cross between white-eyed male *Drosophila* and red-eyed female.  
This is the reciprocal of that shown on Fig. 32.

male, nor can it be carried by the  $Y$  chromosome. The  $F_1$  flies are all heterozygous and red-eyed because every one of them, whether male or female, received the factor for red in the  $X$  chromosome from its mother. All the eggs produced by the  $F_1$  female contain one  $X$  chromosome, but half of these  $X$  chromosomes contain the factor for red, while the other half do not. Of the sperms from the  $F_1$  male half contain an  $X$  chromosome with the factor for red, while the other half contain only a  $Y$  chromosome. When these two series of gametes unite, the result, as shown in Fig. 31, must be that the  $F_2$  females are of two classes, viz. those containing 2 red  $X$  chromosomes, and those containing 1 red and 1 white  $X$  chromosome—in other words, equal number of homozygous and heterozygous red-eyed females. Since the  $F_2$  males received only a  $Y$  chromosome from their father, their nature expresses directly the composition of their  $F_1$  mother, *i.e.* half of them contain a red  $X$  chromosome, and the other half a white  $X$  chromosome. The males of the  $F_2$  generation consist of equal numbers of heterozygous red-eyed and of white-eyed flies. The theory is fully in accordance with the fact that, in the  $F_2$  generation from the cross between a white-eyed male and a red-eyed female, the reds are to the whites as 3 : 1, and the whites are all males. Moreover, as is evident from Fig. 32, it is equally in accordance with the results of the reciprocal cross. Since the cells of the male contain but one  $X$  chromosome, and since the  $X$  chromosome alone can carry the factor for red, every red-eyed male, no matter how bred, must be heterozygous for red.

FIG. 32.

Illustrating cross between white-eyed female *Drosophila* and red-eyed male.  
This is the reciprocal of that shown on Fig. 31.

Hence, when mated with a white-eyed female, all his daughters must be reds, since every individual receiving an  $X$  chromosome from the father must be a female. So also all the sons from such a cross must be white-eyed. For neither the  $X$  chromosome which they receive from the mother, nor the  $Y$  chromosome from the father carries the red factor.

The theory that the manifestation of sex depends upon definite chromosomes—that 2  $X$  chromosomes in the zygote spells a female and 1  $X$  a male—has recently been confirmed in a striking manner by some beautiful experiments of Bridges. He discovered in *Drosophila* a case where the eggs of the female were formed in an abnormal manner. Though most of them contained the normal 4 chromosomes, of which one was an  $X$  chromosome, a few were found which contained 5 chromosomes, and a few in which there were only 3. The former contained a representative of each of the three non-sex chromosomes together with 2  $X$  chromosomes; the latter were without an  $X$  chromosome, containing representatives of the 3 non-sex chromosomes only. Since the sperms of a male are always of two kinds,  $X$  and  $Y$ , these two new classes of eggs ( $XX$  and  $O$ ) led to the possibility of four new classes of zygote, viz.  $XXX$ ,  $XXY$ ,  $OX$ ,  $OY$ . Of these the two kinds  $XXX$  and  $OY$  were not realised, and it is presumed that flies of such constitution are incapable of development. But the  $XXY$  and the  $OX$  zygotes developed into adult flies. The former were females and the latter were males. The females were healthy and normal and produced offspring. So long as

the 2  $X$  chromosomes are present, the presence of a  $Y$  chromosome appears to have no influence upon either sex or fertility. The males, however, all proved to be sterile. A single  $X$  chromosome is sufficient to lead to the production of a male, but it would appear that the presence of a  $Y$  chromosome is essential if the male is to be fertile. Though this chromosome acts as a dummy in so far as the transmission of sex-limited characters is concerned, it nevertheless fulfils some important function in the male economy.

Though the analysis of sex has in no case been pushed so far as in *Drosophila*, we have evidence that sex-limited inheritance of the same type occurs in vertebrates. One of the best known instances is that of the tortoiseshell cat, which, as Doncaster has shown, can be explained on similar lines. It is well known that tortoiseshell cats are almost always females, and experiment has shown that they are the heterozygous

form of black  $\times$  yellow. When a yellow female is mated with a black tom, the male kittens are yellow and the female are tortoiseshell. We may express this by saying that yellow is dominant in the male, but incompletely so in the female. Bred together, such animals give a generation consisting of yellow and of tortoiseshell females, together with yellow and black males in approximately equal numbers. The recessive black reappears in  $F_2$  and, as in the white-eyed *Drosophila*,

FIG. 33.

The chromosomes in the cell of a female containing a  $Y$  chromosome in addition to the 2  $X$  chromosomes normally found in the cells of the female. The  $Y$  chromosome is the hook-shaped one in the lower left part of the figure. (Slightly modified after Bridges.)

is confined to the male sex. If we assume that the heterozygous female is tortoiseshell instead of yellow, the results shown in Fig. 34 are closely comparable to those given in Fig. 27.

FIG. 34.

Scheme illustrating the result of crossing a black tom with a yellow female. Compare with Fig. 27 p. 99.

Moreover, the results of the reciprocal cross are such as might be expected on the theory. The  $F_1$  generation from black female crossed with a yellow ♂ consists of tortoiseshell females and black males. Such animals bred together should give equal numbers of the heterozygous and of the recessive forms in both sexes, and this has been found to be the case (cf. Fig. 35). To this interpretation a difficulty is offered by the existence of tortoiseshell toms. Though they are very rare, there is no question of their occurrence, but at present too little is known about their progeny to enable us to form any clear idea as to their nature. It may not, however, be without significance that in one case, at any rate, an attempt to breed from such an animal proved him to be sterile.

FIG. 35.

Scheme illustrating the result of crossing a yellow tom with a black female. Compare with Fig. 28, p. 100.

The other species of vertebrates that offers examples of what may be termed the *Drosophila* type of sex-limited inheritance is man himself. It is a matter of common experience that

certain defects, colour-blindness for example, are much more common in men than in women. Many pedigrees have now been collected of families in which colour-blinds occur, and the data, with few exceptions, are explicable on the assumptions: (a) that the colour-blind state is recessive to the normal, (b) that it is a character showing sex-limited inheritance, and (c) that the female is the homozygous, the male the heterozygous sex, as in *Drosophila*. If in Figs. 27 and 28 we substitute normal for red eye and colour-blind for white eye, the

schemes given for *Drosophila* will serve to explain the inheritance of colour-blindness in man.

The rarity of colour-blind women is due to the fact that they can only appear from the union between a colour-blind

FIG. 36.

Part of a colour-blind pedigree from Nettleship.

It illustrates the fact that the sons of colour-blind women are all colour-blind, while the daughters, though carriers, are normal. Nothing is known of the father of the two colour-blind women. On theory he should have been affected. That the mother was a carrier is strengthened by the fact that a sister, mated with a normal, produced a colour-blind son among her children.

man and a heterozygous woman, just as the white-eyed female *Drosophila* is only produced from the mating of a heterozygous female and a white-eyed male. Since neither colour-blind men nor heterozygous women (or "carriers" as they are sometimes termed) are common, the chances of a marriage between them are very rare. On the other hand, any female "carrier" mated with a normal male will produce normals and colour-blinds in the ratio 3 : 1, and the colour-blinds in such cases will all be sons. Since the female "carrier" is very much more likely

to marry a normal male than a colour-blind one, we can understand why colour-blindness is so much more common in men than in women. These two different types of sex-limited inheritance lead us to believe that in certain groups of animals, viz. birds and moths, the female is the heterozygous sex, while the converse holds in flies and mammals. Moreover, in *Drosophila* there is definite evidence derived from the nature and arrangement of the chromosomes in favour of this view. Unfortunately the determination of the relations of the chromosomes is very much more difficult in the other groups, owing to their greater number and to the differences between them being far less marked. In the currant moth, where, thanks to Doncaster's researches, more is known than in man or in fowls, the normal number of chromosomes in the body cells is 56, and is the same in both sexes. It has not been found possible to identify any given pair as the sex-chromosomes, for there is no distinctly unequal pair in the heterozygous sex, which in this case is the female. But though the numbers of the sex pair may be visibly indistinguishable, it does not necessarily follow that they are qualitatively so. In *Drosophila* the *X* and the *Y* chromosomes are similar in point of size, and it is quite possible that in some other species the highest powers of the microscope may be unable to distinguish between them. It is conceivable that in the group of cases of which the fowl and currant moth are typical, the pair of sex-chromosomes in the female sex may be qualitatively unequal, and of such a nature that while one of them, like the two sex-chromosomes of

the male, may carry the factors for sex-limited characters, the other may be merely a female determiner incapable of carrying sex-limited factors.

On this hypothesis the silver hen must always be heterozygous for silver. Further, she must transmit her normal sex-chromosome containing the silver factor to a son, and the female determining chromosome which cannot carry silver to her daughter. As indicated in Fig. 37, she would produce, when mated with a gold cock, silver sons and gold daughters. And this, as we have already

seen, is in accordance with the experimental results. An objection to such a view is, of course, that we cannot bring it fully into line with the *Drosophila* case. We cannot say here that 2 *X* chromosomes spell a female, and 1 *X* chromosome a male; a generalisation which in the

FIG. 37.

case of the pomace fly seems well substantiated. At present we must accept the curious position that in one group of insects and one group of vertebrates it is the female sex which is evidently heterozygous, while in another group of insects and another group of vertebrates it is the male sex of which this appears to be true. It is possible that these strange seeming anomalies may be brought ultimately into a general theory of sex when the nature and behaviour of the chromosomes in the other groups have been as fully and as accurately determined as in *Drosophila*.

Sex also occurs among plants but the conditions here are more complicated. Generally speaking, the higher plants are hermaphrodites, both ovules and pollen occurring on the same flower. Some plants, however, like most animals, are of separate sexes, a single plant bearing only male or female flowers. In other plants, as in certain *Begonias* for example, the separate flowers are either male or female, though both are borne on the same individual. In others, again, the conditions are even more complex, for the same plant may bear flowers of three kinds, viz. male, female, and hermaphrodite. Or it may be that two or three forms occur in the same species, but in different individuals—females and hermaphrodites in one species; males, females, and hermaphrodites in another. In comparison with animals, little experimental work has been done with plants in connection with the nature of sex, and we can hardly be said to have begun to understand the relation of the different forms to one another. A few well-established facts, however, are not without interest. In many plants, nominally hermaphrodite, individuals occur in which the anthers are more or less aborted and fail to form pollen. Experimental investigation has shown that in such cases there may be a simple Mendelian relation between the hermaphrodite form with fertile pollen and the female form. In the sweet-pea, and probably in the carnation, the female behaves as a simple recessive to the hermaphrodite; in the potato, however, the evidence points to the hermaphrodite condition being recessive.

In the sweet-pea there is another feature which

is of interest. The peculiar cretin form, described on p. 79, never sets seed though the pods and seeds may often begin to swell; it is always sterile on the female side though the pollen may be perfectly good. When a normal sweet-pea with aborted pollen, practically a female, is fertilised by pollen from a cretin, practically a male, plants with normal hermaphrodite flowers are produced. From these, on self-fertilisation, the four expected classes arise as shown in Fig. 38. Among them is the cretin with sterile pollen, a plant incapable of reproduction either on the male or female side. The proportions in which the four classes appear is peculiar, and will be discussed in detail in the next chapter, when we come to deal with the coupling and repulsion of

FIG. 38.

genetic factors. From the present standpoint it is of interest to note that the majority of the normal fertiles in  $F_2$  behave as the  $F_1$  normal fertile, giving all four classes in the same proportions. Of the normal steriles, again, the majority are homozygous for the normal factor, while the majority of the cretins are homozygous for the factor which leads to the production of fertile pollen. Owing to the peculiar relation between the factors, which will be explained shortly, there is a tendency for the hermaphrodite, produced by the union between a male and a female, to give only males, females, and hermaphrodites. Were the

repulsion between the factors more intense (cf. p. 127) we should obtain an  $F_2$  generation consisting practically entirely of three classes, viz. males, females, and hermaphrodites, which always gave the three forms, male, female, and hermaphrodite in the ratio 1 : 1 : 2. In such cases the true breeding hermaphrodite and the sexless forms would appear only as extreme rarities.

We have instanced this case of the sweet-pea to illustrate how complex a thing sex in plants may be, and how little understood at present. It is not improbable that it may be organised on different lines to those with which we are becoming familiar in animals, but, until we have a far greater body of facts to guide us, speculative interpretations have merely a suggestive value. Up to the present the cytologists have not provided us with any evidence of sex-chromosomes in plants. There is, however, an experiment of Baur with the common *Lychnis*, a plant with separate sexes, which seems to show that sex-limited inheritance may also occur in the vegetable world.

A male individual with narrow leaves was found growing wild. Crossed with a broad-leaved female it gave progeny of both sexes with broad leaves only. In  $F_2$  the narrow-leaved form reappeared as a recessive. All of them, however, were males, though both sexes occurred among the broad-leaved forms. Further experiments by Shull have revealed complications in connection with the proportions of the sexes, and it cannot be said that the case is yet fully understood. Nevertheless, the similarity of Baur's results to those obtained

from the *Drosophila* cross between a red-eyed female and a white-eyed male (cf. p. 99), points to a resemblance between animals and plants in respect of sex.

## CHAPTER XI

### COUPLING AND REPULSION

ALTHOUGH different factors may act together to produce specific results in the zygote through their interaction, yet in all the cases we have hitherto considered, the heredity of each of the different factors is entirely independent. The interaction of the factors affects the characters of the zygote, but makes no difference to the distribution of the separate factors, which is always in strict accordance with the ordinary Mendelian scheme. Each factor in this respect behaves as though the other were not present.

A number of cases, however, have now been worked out in which the distribution of the different factors to the gametes is affected by their simultaneous presence in the zygote. An interesting example occurs in the sweet-pea, in which the phenomenon was originally discovered. It has already been pointed out in Chapter VIII. that, in respect of colour, sweet-peas may be divided into two classes, viz. purples and reds. Purple behaves as a simple dominant to red. The difference between any given purple and the corresponding red is that the

former contains a blue factor ( $B$ ) which is lacking in the latter ( $b$ ). Sweet-peas exhibit an unusual feature in plants, in that they produce one or other of two distinct types of pollen. The majority produce pollen which in the dry state is oblong in shape, and generally spoken of as "long" pollen. In the young state, and when moistened, it is oval and contains 3 pores. In some sweet-peas, however, the young pollen is round instead of oval, and contains but 2 pores. The character of long pollen ( $L$ ) is dominant to that of round ( $l$ ). If a cross is made between a long-pollened purple, such as that illustrated on Pl. IV., 4, and a round pollened red (Pl. IV., 7) the offspring are all long-pollened purples. Nor does it matter which of the two is used as the pollen parent. Such  $F_1$  plants, when self-fertilised, give rise to an  $F_2$  generation consisting of the expected 4 types, viz. : purple long, purple round, red long, and red round.

So far the case runs along ordinary Mendelian lines. Moreover, if we consider each of the two factors concerned separately, the figures are in accordance with expectation. The purples are to the reds as 3 : 1, and so also are the longs to the rounds. It is only when we come to the relative proportions in which these four classes appear in  $F_2$  that a striking difference appears. Instead of the four classes making their appearance in the normal 9 : 3 : 3 : 1 ratio, it is found that the two classes, Purple long and Red round, are greatly in excess of expectation. Nearly 7000 plants have now been raised from this type of mating, and the actual numbers of the four classes obtained are given in

the appended scheme. The figures are obviously

Purple long × Red round				
Purple long				
Purple long	Purple round	Red long	Red round	
4831	390	393	1338	Actual numbers.
4814	408	408	1332	Expectation on
				7 : 1 : 1 : 7 basis.

far from being in accordance with a normal 9 : 3 : 3 : 1 ratio. Nevertheless these numbers, which at first sight appear so irregular, are capable of receiving a simple interpretation. The 9 : 3 : 3 : 1 ratio produced in  $F_2$  by a plant which is heterozygous for 2 factors depends upon the formation by the  $F_1$  plant of 4 types of gamete in equal numbers. If the gametic series given by our  $F_1$  purple were of the form  $BL : Bl : bL : bl$  we should get a 9 : 3 : 3 : 1 ratio in  $F_2$  of the four classes. But if we suppose that the gametes of the two classes  $BL$  and  $bl$  are seven times as numerous as the two classes  $Bl$  and  $bL$  we get an explanation of the peculiar proportions in which the four classes of plant appear in the  $F_2$  generation.

Let us suppose then that the gametes produced by the  $F_1$  purples are of the nature 7  $BL$  : 1  $Bl$  : 1  $bL$  : 7  $bl$ . Such a series of ova fertilised by a similar series of pollen grains will give a generation of the following composition :

$$\begin{array}{r}
 49 \text{ } BBLl + 7 \text{ } BBll + 7 \text{ } BbLL + 49 \text{ } BbLl \\
 + 7 \text{ } BBLl + 7 \text{ } BbLL + 1 \text{ } BbLl \\
 + 1 \text{ } BbLl \\
 + 49 \text{ } BbLl \\
 \hline
 177 \text{ purple long}
 \end{array}$$

$$\begin{array}{rcc}
 +1\ BBll + 7\ Bbll + 1\ bbLL + 7\ bbLl + 49\ bbl \\
 \quad \quad \quad + 7\ Bbll \quad \quad \quad + 7\ bbLl \\
 \hline
 \begin{array}{ccc}
 15\ \text{purple} & 15\ \text{red} & 49\ \text{red} \\
 \text{round} & \text{long} & \text{round}
 \end{array}
 \end{array}$$

The  $F_2$  generation should consist of the 4 classes, purple long, purple round, red long, and red round in the proportions 177 : 15 : 15 : 49. The sum total of the plants bred in this way was 6952. On the hypothesis outlined above we should expect it therefore to consist of 4814 purple longs, 408 purple rounds, 408 red long, and 1332 red rounds. A glance at the scheme given on p. 120 shows how closely this expectation tallies with the experimental results. Corroborative evidence was also obtained by crossing red round plants, with the pollen of the  $F_1$ . This method of crossing with the double recessive affords a direct test of the nature of the gametic series produced in the ratio 7 : 1 : 1 : 7, and the actual numbers obtained, viz. 50 purple longs, 7 purple rounds, 8 red longs, and 47 red rounds again, tally closely with expectation.

A sweet-pea heterozygous for  $B$  and  $L$  may arise in two different ways—either through the union of a  $BL$  gamete with a  $bl$  one, or else by the union of  $Bl$  with  $bL$ . The former case we have just discussed: let us now consider what happens in the latter. When a purple round is crossed with a red long the  $F_1$  plants are long-pollened purples as before. The  $F_2$  generation thus consists of the 4 possible classes of plants as before, and as before the purples are to the reds as 3 : 1, as also are the longs to the rounds. But the proportion in which the four classes occur now shows a marked difference.

The purple longs form about one half of the total, the purple rounds and the red longs each form about one quarter, while the red rounds are extremely rare. Far fewer plants have been raised from this mating than from the preceding one, but the appended scheme, in which are given the actual figures obtained, shows clearly how widely they depart from the former case.

Here again we can explain these peculiar proportions by a simple assumption. If we suppose that the  $F_1$  purple, arising from the cross between a purple round and a red long, forms a series of gametes of the nature 1  $BL$  : 7  $Bl$  : 7  $bL$  : 1  $bl$ , instead of in equal numbers we can understand the peculiar proportions in which the four classes of the  $F_2$  generation appear. For such a series of ova fertilised by a similar series of pollen grains will give a generation of the following composition :

$$\begin{array}{r}
 1 \text{ } BBLl + 7 \text{ } BB Ll + 7 \text{ } Bb LL + 1 \text{ } Bb Ll \\
 \quad \quad \quad + 7 \text{ } BB Ll + 7 \text{ } Bb LL + 49 \text{ } Bb Ll \\
 \quad \quad \quad \quad \quad \quad + 49 \text{ } Bb Ll \\
 \quad \quad \quad \quad \quad \quad + 1 \text{ } Bb Ll \\
 \hline
 129 \text{ purple long} \\
 + 49 \text{ } BB ll + 7 \text{ } Bb ll + 49 \text{ } bb LL + 7 \text{ } bb Ll + 1 \text{ } bb ll \\
 \quad \quad \quad + 7 \text{ } Bb ll \quad \quad \quad + 7 \text{ } bb Ll \\
 \hline
 \underbrace{63 \text{ purple round}} \quad \quad \underbrace{63 \text{ red long}} \quad \quad \underbrace{1 \text{ red round}}
 \end{array}$$

The  $F_2$  generation should consist of the four classes purple long, purple round, red long, and red round in the proportion 129:63:63:1. In other words the first three of the four classes should be found closely in the ratio 2:1:1, while the remaining class, the red rounds, should only occur once in every 256 plants. The experimental figures given in the scheme on p. 122 show that this condition is closely fulfilled.

In considering these two series of experimental results together, there is one feature which stands out prominently. In each case the majority of the gametes produced by the  $F_1$  plant are of the same kind as the two gametes through whose union the plant itself was formed. The  $F_1$  plant formed by the gametes  $BL$  and  $bl$  gives rise to seven times as many gametes of these two types as of the types  $Bl$  and  $bL$ . The  $F_1$  plant formed by the gametes  $Bl$  and  $bL$  gives rise to seven times as many gametes of these two types as of the types  $BL$  and  $bl$ . And this is true of other cases where this peculiar interrelation of the factors has been investigated. In all such cases the plant which is heterozygous for the factors showing this relation, produces a majority of gametes of the two parental types. In the earlier days of the study of this phenomenon it was customary to speak of it in terms of the "coupling" and "repulsion" of factors. When the nature of the cross was such that both of the factors  $B$  and  $L$  entered from one parent, and neither of them by the other parent—when the cross was of the nature  $BL \times bl$ —the factors  $B$  and  $L$  were said to exhibit partial coupling. In the formation of

gametes by the  $F_1$  plant, they tended to enter into the same gamete seven times as often as they entered into different ones. So also when the cross is of the nature  $B l \times b L$  the  $F_1$  plant is of the same constitution, viz.  $B b L l$ . But the majority of the gametes formed are of the nature  $B l$  and  $b L$ . The two factors pass into different gametes seven times as frequently as they enter into the same one. During the gametogenesis of the  $F_1$  plant they appeared to repel one another, though not in every case, whence originated the term partial repulsion. At the time when these terms were proposed it was not understood that both coupling and repulsion were essentially part of the same phenomenon. More recently the term "reduplication" has been brought into use. In the gametic series  $7 BL : 1 Bl : 1 bL : 7 bl$  the terms  $BL$  and  $bl$  are said to be reduplicated: in the series  $1 BL : 7 Bl : 7 bL : 1 bl$  reduplication is shown by the terms  $Bl$  and  $bL$ . The term is not altogether satisfactory, for biologists are not at present in agreement as to the manner in which these gametic series come to be formed. For the moment we may continue to use the terms coupling and repulsion provided that we remember they are essentially part of the same process.

In the case of the factors which we have been discussing, the preponderance of the parental types of gamete was as  $7:1$ . But it differs widely for different characters even in the same species as the following examples serve to illustrate. In some sweet-peas the anthers are sterile, setting no pollen, and this condition is recessive to the ordinary fertile condition. Again there is a peculiar monstrous

form of flower known as the cretin (Fig. 17) which is recessive to the normal flower. The factors for normal ( $N$ ) as opposed to cretin ( $n$ ) and fertile pollen ( $F$ ) as opposed to sterility ( $f$ ) exhibit the phenomenon of coupling and repulsion. When a normal sterile is crossed with a cretin fertile, the  $F_1$  plants are all normal fertiles.

			Actual numbers.
			Expectation on
			1 : 3 : 3 : 1 basis.

In  $F_2$  the four possible combinations appear, but in proportions suggesting that the gametic series formed by the  $F_1$  plant is of the nature 1  $NF$  : 3  $Nf$  : 3  $nF$  : 1  $nf$ . Such a series would give the four classes in the ratio 33 : 15 : 15 : 1—a ratio closely fulfilled by the experimental results as is shown in the appended scheme. Further, when the normal fertile  $F_1$  is produced by the union of a normal fertile gamete with a cretin sterile one ( $NF \times nf$ ) coupling occurs in  $F_2$  between  $N \times F$ , so that the gametic series must here be supposed to be of the form 3  $NF$  : 1  $Nf$  : 1  $nF$  : 3  $nf$ . In the case of these two factors the value of the coupling and repulsion is lower than in the case of the factors for blue and long pollen. It is on a 3 : 1 instead of on a 7 : 1 basis.

In other cases, however, the intensity of the

coupling and repulsion may be much higher. We have already seen that the erect standard in the sweet-pea (p. 78) is dominant to the hooded standard (cf. Pl. II., 7), and we assume that the former contains a factor for the erect character ( $E$ ) which is lacking in the latter ( $e$ ). Now the factor for erect standard exhibits the phenomenon of coupling and repulsion with the factor for blue ( $B$ ). If we make a cross between a purple erect sweet-pea and a red-hooded one the offspring are all purple erect.

Purple erect × Red hooded

2023	11	11	667	Expectation on
				127:1 basis.

A considerable number of  $F_2$  plants have been raised from such a cross, and as the appended scheme shows they consist almost entirely of the two parental forms. Nevertheless a few purple hooded and red erect plants make their appearance. The proportions in which they appear fit closely with the assumption that the gametic series produced by the  $F_1$  plants is of the nature  $127 BE : 1 Be : 1 bE : 127 be$ . The intensity of the coupling is here very much higher than in the cases considered above. For this reason the cross of the opposite nature—purple hooded × red erect—presents a feature of some interest. If, on analogy, we suppose the gametic series produced by the  $F_1$  purple erects to

be of the nature  $1\ BE:127\ Be:127\ bE:1\ be$ , it is clear that we can look for the appearance of the red-hooded class only as a great rarity. To be exact we should expect a plant of this class to appear once among 65,536 ( $= 256^2$ ) individuals in the  $F_2$  generation. Unless impracticably large numbers are bred we should expect the  $F_2$  generation to consist of the three forms—purple erect, purple hooded, and red erect in the proportion  $2:1:1$ . And this is what has actually happened. Among 5789 plants bred in this way

no red hood has appeared, while the three classes found are roughly in the proportion  $2:1:1$ . Moreover the hypothesis demands that almost all of the  $F_2$  purple erects should behave as the  $F_1$  plants, that almost all the purple hooded should be homozygous for  $B$ , and that almost all the red erects should be homozygous for  $E$ . In other words, the great majority of the purple hooded and of the red erect should breed true, while the purple erects should almost invariably throw all three forms. This natural consequence of the high intensity of the repulsion suggests a comparison with such cases as that of the Andalusian fowl (p. 64). Here also we have three forms of which two breed true while the other throws birds like itself, and birds like each of

the two true breeding forms in the ratio 2 : 1 : 1. We took the view that the blue is the heterozygous form ; that the presence or absence of a single Mendelian factor only is concerned in this instance. Nor in the light of such facts as we possess is there anything to contradict this view. Nevertheless, in the light of what has been learned from the sweet-pea, we may do well to remember that the case of the Andalusians may not really be so simple as it appears at first sight. It is not inconceivable that two factors are concerned, and that the blue is heterozygous for both of them. Were this so, and were the two factors to exhibit repulsion of a high intensity, perhaps even higher than that found for the factors *B* and *E* in the sweet-pea, it would accord with the general results obtained in Andalusian breeding. The criterion between this view of the case and the one taken earlier would be the rare appearance of a fourth form; comparable to the red hood in the sweet-pea. So far we have no evidence that such a form exists, and until it is found we may leave the blue Andalusian fowl undisturbed in its claim to simple heterozygosity.

We may now go on to consider a further complication connected with this phenomenon of coupling and repulsion. This relation exists between the factors for blue (*B*) and for long pollen (*L*) in the sweet-pea. But, as we have seen, it exists also between the factors for blue (*B*) and for the erect standard (*E*). Since *L* and *E* both bear a similar relation to (*B*) the question naturally occurs—What relation do they bear to one another? Experimental data for answering this question have been

obtained during the past few years, and we now know that the relation between  $E$  and  $L$  is similar to that existing between  $B$  and  $L$ . When a cross is made between a plant with erect standard and long pollen, and one with hooded standard and round pollen, the colour being the same in both cases, the  $F_1$  plants are all long pollened and erect. In  $F_2$ , as the appended scheme shows, the four expected classes are produced in proportions which tally closely with the hypothesis that the gametic series produced by the  $F_1$  plants is of the nature  $7 EL : 1 El : 1 eL : 7 el$ .

Erect long × Hooded round				
Erect long				
Erect long	Erect round	Hooded long	Hooded round	
765	62	71	220	Actual numbers.
773	65.5	65.5	214	Expectation on 7:1 basis.

Of the three factors  $B$ ,  $E$ , and  $L$ , any given pair exhibits the phenomenon of coupling and repulsion, where the plants are homozygous in respect of the third factor. What happens in the case of plants which are heterozygous for all three factors? There are four different ways in which such plants can be made, viz.:

$$\begin{aligned}
 & BeL \times bEl \\
 & BEl \times beL \\
 & bEL \times Bel \\
 & BEL \times bel
 \end{aligned}$$

According to the manner in which they are

produced so do the proportions of the eight possible classes of plants differ. But the general rule already laid down, that the majority of the gametes are of the parental types holds good here also. When two factors go into the cross from the same parent they show coupling in gametes produced by the  $F_1$  plants: when they enter the cross from opposite sides they exhibit repulsion when the  $F_1$  gametes come to be formed. For example, in the cross of a purple-hooded long with a red-erect round,  $BeL \times beL$ , there is coupling between the factors  $B$  and  $L$  but repulsion between  $B$  and  $E$ , and between  $L$  and  $E$ . The two commonest types of gamete formed are the  $BeL$  and the  $beL$  types. But there are also found a few gametes of the other possible types, viz.  $Bel$ ,  $bEL$ ,  $BEL$ ,  $bel$ ,  $BEl$  and  $beL$ . The last four types are, however, extremely rare. So also in the cross between an erect purple long and a hooded red round,  $BEL \times bel$ , all of the possible eight types of gamete are found, but the two parental types  $BEL \times bel$  are far more numerous than any of the others. This is evident from the nature of the  $F_2$  generation, of which the following particulars for 1803 individuals are available:

$\left. \begin{array}{c} \text{Erect} \\ \text{purple} \\ \text{long} \end{array} \right\} \times \left\{ \begin{array}{c} \text{Hooded} \\ \text{red} \\ \text{round} \end{array} \right.$							
Erect purple long							
Erect	Erect	Hooded	Hooded	Erect	Erect	Hooded	Hooded
purple	purple	purple	purple	red	red	red	red
long	round	long	round	long	round	long	round
1196	100	7	5	3	7	112	373

The most numerous classes are those resembling the original parents, but all of the possible eight types of plant are represented, though some are very rare.

The case of what we may term the *B, E, L* series is not the only one in which the members of a little group of factors behave towards one another in this peculiar way. We have already mentioned (p. 79) that the factor for normal flower (*N*) as opposed to cretin, and that for the fertile anther (*F*) as opposed to sterile, behave in the same way. To these two factors we may add a third. In some sweet-peas the axil from which the leaf stalk springs is purple-red in colour, while in others it is green.<sup>1</sup> The former, the dark axil, is dominant to the light axil. The factor for dark axil *D* exhibits the phenomenon of coupling and repulsion with either of the two factors, *N* or *F*. The *D, F, N* series behaves similarly to the *B, E, L* series, though the intensity of the coupling values is widely different in the two cases. It should be added that, so far as we know at present, the two series are quite independent of one another.

Since the phenomenon was discovered in the sweet-pea other examples have been found both in plants and animals. It has been described in *Antirrhinums*, in *Primulas*, in peas, wheat, maize, and rats. In no species, however, has it been worked out with such wealth of detail as in the pomace fly (*Drosophila ampelophila*); but the im-

<sup>1</sup> The axil is always green in pure white-flowered varieties, *i.e.* those which have light seeds. Such whites, however, may carry the factor for the dark axil, and when crossed with a light axilled coloured plant the dark axil appears in their progeny.

portant influence which that little creature is now exerting on the science of genetics must be reserved for another chapter. Meanwhile it is clear that the phenomenon is of very great importance. Apart from the light it may be expected to shed upon the architecture of the cell and upon the mechanics of cell division, it is likely to help us in understanding many a puzzling group of facts. Those who attempt to interpret what is known of inheritance in man in terms of the facts of Mendelian heredity must often have encountered the difficulty of the remarkable resemblance so often found between parent and offspring. Civilised man is such a mongrel; teeming with heritable characters, yet so hopelessly heterozygotic, that he might well be the despair of any bold enough, even in thought, to isolate pure strains of human beings. Nevertheless, how often do we find that one child is extraordinarily like the father, while another closely resembles the mother. Were all of the separately heritable characters transmitted entirely independently of one another, these cases of close resemblance should be rare. The fact that they are so numerous suggests that in man factors are transmitted as it were in bunches, and it is not improbable that the study of cases in which coupling and repulsion occur, will eventually render more clear what is evidently an important feature in the heredity of our own species.

## CHAPTER XII

### THE CHROMOSOME THEORY

OF the more recent developments in Mendelism, none have excited so much interest or been so productive in results as those associated with the names of Morgan and his colleagues in America. With some of these we have already dealt in connection with sex. The little fruit fly, *Drosophila ampelophila*, with which they worked, is the most favourable material yet found for unravelling the problems of heredity. It already offers more than 100 factors which appear to exhibit Mendelian segregation: its chromosomes are distinct and few in number: it is both hardy and prolific: it is easily dealt with in the laboratory as it takes up little space, and it is cheap to work with, since thousands may be reared at the cost of a few rotten bananas. During the past ten years these advantages have been fully exploited by the American workers, and their results have led them to formulate what is known as the chromosome theory of heredity. According to this theory the chromosomes form the material basis of heredity. The various factors upon which the manifestation of characters depend

are resident in the chromosomes, whence they influence the nature of the cells and of the organism which the cells go to build up. How the phenomena of segregation can be brought into line with the phenomena exhibited by the chromosomes in the formation of the gametes will necessitate a brief digression.

The number of the chromosomes in the cells of an animal or plant is normally a constant number which is some multiple of two. This is because one half of the chromosomes is derived from each gamete of which the new individual is found. When the sperm and the egg fuse, the number of chromosomes in the zygote so formed is double that contained in either of the gametes. The chromosomes of a gamete often differ in size and shape, and when this is so every gamete, whether egg or sperm, contains a corresponding series of chromosomes.<sup>1</sup> The zygote therefore possesses a paired series of chromosomes corresponding to the single series in the gamete. Let us now take a simple imaginary case in which the gamete contains two chromosomes, one long and one short one (Fig. 39). Further, we will distinguish the maternal and paternal chromosomes, *i.e.* those brought into the zygote by the egg and the sperm respectively, by different methods of shading in the diagram. A zygote results with 4 chromosomes, a pair of long ones and a pair of short ones. By repeated divisions this zygote grows into a plant or animal as the case may be. At every division each chromosome is halved, and each of the

<sup>1</sup> Apart from the peculiar sex-chromosomes already alluded to on p. 102.

halves becomes a complete chromosome, so that all of the resulting cells contain 4 chromosomes like the original zygote. But when the time comes to form gametes, a peculiar process occurs by which the number of the chromosomes in each gamete is

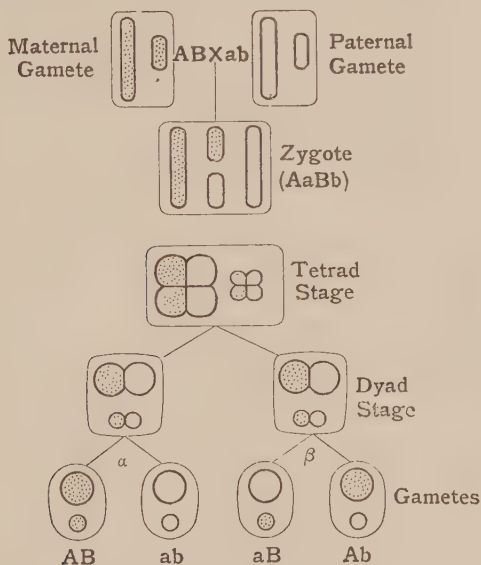

FIG. 39.

Scheme illustrating the distribution of the maternal and paternal chromosomes in the families formed by the  $F_1$  zygote. Further explanation in text.

reduced to 2. In the cells which are destined to form the gametes the corresponding chromosomes pair closely with one another, often giving rise to bodies known as the tetrads. Then follow two rapid divisions by which the chromosome material is first reduced to one half, and next to one quarter of

that found in the tetrad stage. As is shown in Fig. 39, we may suppose that the first division is merely quantitative, resulting in two cells each containing a representation of the two maternal and of the two paternal chromosomes. The second division, however, we must suppose to be qualitative, the maternal and paternal portion both of the long and of the short chromosomes separating from one another. This may occur in two different ways.

The maternal part of the long gamete may be associated with the maternal part of the short gamete (as shown in  $\alpha$ ), in which case the paternal part of the long gamete must be associated with the paternal part of the short gamete; or (as shown in  $\beta$ ) the maternal part of the long gamete may be associated with the paternal part of the short one, in which case the paternal part of the long one must be associated with the maternal part of the short one. As to which of these two things happens the chances are equal. Consequently the gametes produced, as shown in the bottom line of Fig. 39, are of four different kinds which are found in equal numbers.

Let us now suppose that our original maternal gamete contained two Mendelian factors  $A$  and  $B$ , one in each chromosome, and that the paternal gamete contained neither. The zygote must be of the constitution  $Aa, Bb$ , and should produce equal numbers of gametes of the four kinds,  $AB, Ab, aB, ab$ . Clearly this is in accordance with the chromosome theory, provided we assume that each different factor is carried in a different pair of chromosomes.

In the earlier days of Mendelian studies the close

parallel between the behaviour of the chromosomes and the segregation of factors led to the suggestion that the chromosomes might themselves be the factors. It was not long, however, before the view was seen to be too crude. As the work went on, it became apparent that the number of factors exhibiting Mendelian segregation in a species may be considerably greater than the number of chromosomes. On the chromosome theory, therefore, some, if not all, of the chromosomes must carry more than one factor. This introduces a difficulty. Let us suppose that in the imaginary case we have just been discussing, the long maternal chromosome carries two factors *A* and *C*, while the short one carries *B*. Since the chromosomes must be supposed to preserve their individuality, and of this there is independent evidence from other sources, it is clear that *A* and *C* must always remain completely linked together. If we find that they can be separated, we must either give up the chromosome theory altogether, or find some acceptable explanation.

It is to meet this difficulty that the American workers have devised a very ingenious hypothesis. In *Drosophila* there is evidence for over 100 different factors, while the number of chromosomes in the gamete is only 4 (cf. Fig. 30, p. 104). Large numbers of experiments, involving the breeding of hundreds of thousands of flies, have shown that the numerous factors already demonstrated in *Drosophila* fall into four groups. The members of any one of these groups exhibit towards one another the phenomena of coupling and repulsion, or, as it is generally termed in America, **linkage**. Between

the members of different groups there is said to be no evidence of this phenomenon of linkage. The inference is that these four groups of factors correspond to the four pairs of chromosomes. This view is supported by the following considerations. In the first place, the four groups of factors are far from equal in number. Three of them contain many more factors than the fourth one, in which but three have so far been identified. This is what

FIG. 40.

Diagram to illustrate the linear arrangement of the factors in Chromosomes I.-IV. of *Drosophila*. The number of separate factors must be supposed to be very much greater than is represented.

might be expected from the fact that one of the pairs of chromosomes (Chromosome IV.) is a very small one. Secondly, one of the groups consists of factors which all exhibit sex-linked inheritance, while factors of this nature do not appear in any of the other three groups. This is comprehensible if it is assumed that this group of factors is carried by the sex-chromosome (Chromosome I. in Fig. 40).

An important point is the arrangement of the factors in the chromosome. This is assumed to be

locus

first-named is dominant. When a black fly with vestigial wings is crossed with a grey normal the offspring are all grey normals, the result being the same whether the black vestigial is used as the male or the female parent.

When the  $F_1$  ♂ is mated back with the double recessive, the black vestigial female, he produces only two types of offspring, viz. grey normals and black vestigials in equal numbers. This is what would naturally be expected on the chromosome theory in its simplest form. For of the two chromosomes belonging to the second pair that he contains, one was derived from a grey normal, and the other from a black vestigial parent. Consequently, when these chromosomes separate again in the formation of the gametes we should expect half of these to contain the grey normal chromosome, and the other half the black vestigial one. The result of crossing the  $F_1$  ♂ back with the double recessive clearly indicates that this is what happens. The factors for grey and normal wing remain together, thus conforming to the view that the integrity of the chromosome, in which both occur, is preserved.

When, however, we turn to the behaviour of the  $F_1$  ♀ we find a different state of affairs. The result of crossing her with the double recessive, the black vestigial male, is to lead to the production of four kinds of offspring, viz. grey normal, grey vestigial, black normal, and black vestigial. The two classes grey normal and black vestigial are about four times as numerous as the other two classes, grey vestigial and black normal. Evidently

this is the phenomenon we have already described as coupling, in which the  $F_1$  produces an excess of the two types of gamete that went to its own making—in this case grey normal and black vestigial. But if the factors for grey and normal wing are situated in the same chromosome, how comes it that the  $F_1$  ♀ produces any of the other two types of gamete, the grey vestigial and the black normal, in which the factors for grey and normal have become dissociated from one another? Why is the behaviour of the  $F_1$  ♀ so different from that of her brother? The American observers have sought to surmount this difficulty by an ingenious hypothesis which provides for the interchange of material between the paternal and maternal members of the pair of chromosomes. The cells of an individual contain, as we have already seen, a double set of chromosomes, there being as many pairs of chromosomes in each of these cells as there are single chromosomes in the gamete. Of each pair in the double set one is derived from the paternal and the other from the maternal gamete. When a cell divides to form two daughter cells each individual chromosome is halved, so that in respect of the number and constitution of the chromosomes the daughter cells are like their mother cell and like each other. In order to interpret linkage of factors it is supposed that at certain stages preceding the formation of gametes there is a transference of material from one chromosome of any given pair to the other. No such transference, however, takes place between chromosomes belonging to different pairs. The explanation will perhaps

be more easily followed by means of a definite example, and for this purpose we may take the behaviour of the factors for grey body-colour and for normal, as opposed to vestigial wings, in the  $F_1$  ♀ *Drosophila* discussed above. The factors are found in Chromosome II., and it is supposed that they are both located towards the middle of the chromosome, and separated from one another by about  $\frac{1}{6}$  of the length of the chromosome as indicated in Fig. 42. Let us suppose that at a certain stage preceding the formation of the gametes, when the two members of the pair come to be in intimate contact along their whole length, they tend to cross over one another as in Fig. 42. Further, let us suppose that they fuse at the point where they cross over one another, and that when they subsequently separate, they exchange that portion of the chromosome which lies beyond the point of junction. The result of this will be that our pair of chromosomes will now be constituted in the manner indicated in Fig. 42.

But as the point of junction is here beyond that portion of the chromosome which lies between  $G$  and  $N$ , the association between these two factors will not be disturbed. If, however, the point of junction is between  $G$  and  $N$ , as in Fig. 42 C, the separation of the chromosomes will bring about a separation between  $G$  and  $N$ . Instead of being left with a grey normal and a black vestigial chromosome, we shall now have a grey vestigial and a black normal one. The process of "crossing-over," as it is called, results in the production of gametes unlike those of the two parental types which

went to form the  $F_1$  female. Further, if we suppose that the point of junction may occur with equal

FIG. 42.

Diagram illustrating the process of "crossing-over" between paired chromosomes. When the point of junction is situated as in *A* or *B*, the gametes formed are "non-crossover" gametes in respect of the factors *G* and *N*. When the point of junction is situated as in *C*, the gametes formed are "cross-over" gametes in respect of *G* and *N*.

likelihood at any point along the chromosomes it is clear that the chance of two factors becoming

separated in this way depends upon the distance which separates them in the chromosomes. The nearer they are together, the less likely are they to become separated: the further apart they are, the more often is separation likely to occur. It is upon the proportion of "crossover" gametes as compared with "non-crossover" gametes that the distances between the factors along the chromosomes have been determined, always on the assumption that the factors are arranged along the chromosome after the fashion of beads along a string. Thus in the particular instance under discussion, the female *Drosophila* formed by the union between a grey normal and a black vestigial gamete, the crossover gametes, viz. grey vestigial and black normal, form about  $\frac{1}{6}$  of the total. The inference is that the distance between the grey factor and the normal-wing factor is about  $\frac{1}{6}$  of the length of the chromosome. In the same way the position of other factors in Chromosome II. has been determined with respect to those for grey body-colour and for normal wing. Using this method, the American observers have constructed a map of each of the four chromosomes, showing the precise position along each one at which the various factors occur, and it is claimed that these maps are based upon a very large and fairly consistent body of experimental facts.

The explanation will of course serve equally well to account for what we have previously termed repulsion, as well as for coupling. When the union between a grey vestigial and a black normal gamete takes place the  $F_1$  flies are grey normals as before. On

mating the  $F_1$  females with black vestigial males the resulting generation consists, as before, of the four types, grey normals, grey vestigials, black normals, and black vestigials. But it is now the grey vestigials and the black normals which outnumber the other two classes by about 5 to 1. These are of course the two original parental types, and the explanation of their appearance in excess of the two non-parental types lies, as before, in the excess of the non-crossover gametes produced as compared

FIG. 43.

For explanation see text.

with crossover ones. In the case of the  $F_1$  male too the result is strictly comparable with that noticed in the preceding cross. When mated with the double recessive, the black vestigial female, he produces only grey vestigial and black normal offspring in approximately equal numbers. It must be inferred that the male produces only the two parental types of chromosome, and that no crossing over occurs in this sex. This is true, not only of the particular case under discussion, but of all cases where the constitution of the male has been investigated by this method. Why this crossing over

should occur in the one sex, but not in the other, is at present unexplained.

If it were found by direct observation that the behaviour of the chromosomes differed in the two sexes, we should be furnished with substantial evidence in support of the chromosome theory. But at present we are without grounds for this assumption. Indeed it should not be forgotten that the postulated twisting of the chromosomes on one another, though observed in some animals, has never yet been demonstrated for the female of *Drosophila*. The technical difficulties are doubtless very great, yet until this demonstration has been provided there must necessarily remain a gap in the chain of evidence by which the chromosome theory is supported.

To attempt to follow the theory in all its implications would lead us far beyond the scope of this little book. There are many difficulties in the way which must be cleared up before it can be accepted without reserve. So far it is based entirely upon the *Drosophila* work, in which it is claimed that the number of the groups of factors exhibiting the relation of linkage is equal to that of the number of chromosomes in the gamete. If it were discovered that in any animal or plant there existed a number of factors, or groups of factors, without linkage relations, greater than the gametic number of chromosomes, the theory would necessarily fall to the ground. No genetic material hitherto used gives such quick returns as *Drosophila*, and probably some years must elapse before we can hope for definite evidence from other forms of life. Until this is forthcoming it is perhaps as well to exercise

caution in accepting a theory of which the consequences are so important and far reaching.

One further point may here be mentioned, viz. the bearing of the chromosome theory upon the Presence and Absence hypothesis. If each factor is represented by a definite portion of the length of a chromosome—if the factors form a linear series in the manner of a string of beads—then it is clear that the Presence and Absence hypothesis, in the sense that a definite portion of the chromosome length may be present or absent, cannot be supposed to hold good. Otherwise a chromosome bearing the factors for a number of dominant characters would be longer than the corresponding one which did not carry these factors. The strings that had to pair with one another would be of unequal length: corresponding factors would no longer find themselves exactly opposite one another, and disorder would result in the process of crossing over. On the chromosome theory it must be supposed that each member of a given pair is always made up of the same number of the portions which correspond with factors. This had led to the conception that the recessive character is also represented by a definite factor occupying a definite portion of the length of the chromosome, just as the factor for the dominant character does. There is a definite factor for black body-colour in *Drosophila* as well as for grey, and a definite factor for vestigial wings as well as for normal ones. In this way we are provided with a recessive factor in the position required for interchange with the corresponding dominant factor when crossing over takes place between the chromosomes.

But the conception underlying the Presence and Absence theory is not necessarily destroyed. It is open to us to regard the segments of the chromosomes as containers, differing in their content according as they correspond to the factor for a recessive or for a dominant character. The container of the factor for grey body-colour may have all the constituents to be found in the container of the factor for the recessive black body-colour, and at the same time may contain the additional constituent which decides that the colour shall be grey. Were some such idea adopted it would of course be necessary to distinguish between the container, the constituents which the dominant and recessive factors possess in common, and the constituent which is found in the dominant factor alone. Some revision of nomenclature would be required, especially with regard to the precise meaning to be attached to the term factor. While, however, the nature of the machinery is so largely a matter of speculation, it seems hardly necessary to invent terms for its special parts.

## CHAPTER XIII

### CERTAIN COMPLICATIONS

IN the light of our present knowledge of heredity the analysis of a plant or animal—the determination of the factors upon which the various characters depend—is often a simple process though it may be a laborious one. Were any one fired with the ambition of providing a complete factorial analysis of all of the colours and shades that occur in the flowers of the sweet-pea, he would probably encounter few difficulties. Given an eye for shades of colour, perseverance, and an elementary knowledge of the principles of Mendelian heredity, he should be able to furnish every form of flower with its appropriate formula of factors within a reasonable time. But it not infrequently happens that unexpected complications appear, obscuring an analysis pursued in the orthodox way. A trained investigator to-day, starting to explore the genetic constitution of a creature by the methods of cross-breeding, would in all probability frame some working hypothesis at an early stage in his experiments. The nature of an  $F_1$  generation, the numbers and proportions of the different forms in  $F_2$ , would at once suggest in-

ferences as to the factors involved in connection with the characters which he was investigating. He would then set to work to test his hypothesis by devising specific tests to settle specific points. It might be that the example which he had chosen offered no special difficulty to a complete and simple factorial analysis. In such a case he would thenceforward be in a position to control the characters so analysed, and to build up strains of any combination that he wished. Fortunately for the investigator, however, plain sailing of this sort is by no means the rule. His working hypothesis is often wrecked by an unsuspected snag. He is up against some fresh phenomenon, and the work at once becomes more interesting. For the unexpected brings with it the hope of discovery. It is the object of this chapter to give a few illustrations of the occurrence of the unexpected, and of the way in which it has been met.

Many of the earlier experiments with animals were made with fancy mice. Their many shades of coat colour, the rapidity with which they could be bred, and the small cost of keeping them, marked them out from the first as suitable material for genetic work. Among the various colours used was yellow, and it was not long before Cuénot showed it to be dominant to any other colour used. Crossed with any other colour, heterozygous yellows threw equal numbers of yellows and non-yellows. But when such heterozygous yellows were mated together it was found that although they gave many more yellows than other colours, the proportion of yellows was not as great as that expressed by the

ratio 3 : 1. Further, it was found that no homozygous yellows were produced from the mating of yellow  $\times$  yellow, though, on simple Mendelian expectation, one out of every three from such a mating should have been of this nature. Why were no homozygous yellows formed? A suggestion was made that there was some form of selective fertilisation of such a nature that a "yellow" sperm refused to fertilise a "yellow" ovum. It was, however, pointed out that "yellow" ova manifested no antipathy to "non-yellow" sperm: that if this hypothesis were true all of the "yellow" ova would be fertilised by "non-yellow" sperms, of which there was a superabundance. Hence all of the "yellow" ova would give heterozygous yellows, while of the "non-yellow" ova one half would give heterozygous yellows, and the other half non-yellows. And as "yellow" and "non-yellow" ova are produced in equal numbers, the net result of a mating between two yellows should be yellow: non-yellows in the ratio of 3 : 1. But the many hundreds of mice bred from yellow  $\times$  yellow had established the fact beyond question that the proportion of yellow to non-yellow was 2 : 1. The hypothesis naturally fell to the ground, and it was then suggested that the facts would be explained if it were supposed that the "yellow" sperm could fertilise the "yellow" egg, but that the resulting zygote, the homozygous yellow, was incapable of developing sufficiently far to be born. It was pointed out in support of this that litters from two yellows were, on the average, smaller than between yellow  $\times$  non-yellow; as indeed would be expected if the homozygous yellows perished

early in the uterus. Quite recently additional confirmation has been forthcoming from the work of several American investigators. They have found that when the uterus is opened during the earlier part of pregnancy, dead embryos are much more numerous in yellow females that have been mated with yellow males, than in yellow females bred to non-yellow males. The unexpected complication arising from the failure to realise the looked-for 3 : 1 ratio, when heterozygous yellows were bred together, led to the interesting and important discovery that certain gametic combinations may lead to the formation of a zygote which, for no apparent reason, is doomed to perish prematurely. Since the discovery of this phenomenon in the mouse, evidence has come to light that it occurs also in *Drosophila*, and it is not unlikely that it may prove to be widespread in both animals and plants.

For another interesting complication we may turn to plants. In the common English bryony (*Bryonia dioica*) the sexes are separate, some plants having only male, and others only female flowers. In another European species, *B. alba*, both male and female flowers occur on the same plant. Correns crossed these two species reciprocally, and also fertilised *B. dioica* by its own male with the following results :

dioica ♀	× dioica ♂	gave	♀ ♀ and ♂ ♂
„	× alba ♂	„	♀ ♀ only
alba ♀	× dioica ♂	„	♀ ♀ and ♂ ♂.

The point of chief interest lies in the striking difference shown by the reciprocal crosses between *dioica*

and *alba*. Males appear when *alba* is used as the female parent but not when the female *dioica* is crossed by male *alba*. It is possible to suggest more than one scheme to cover these facts, but we may confine ourselves here to that which seems most in accord with the general trend of other cases. We will suppose that in *dioica* femaleness is dominant to maleness, and that the female is heterozygous for this additional factor. In this species, then, the female produces equal numbers of ovules with and without the female factor, while this factor is absent in all the pollen grains. *Alba* ♀ × *dioica* ♂ gives the same result as *dioica* ♀ × *dioica* ♂, and we must therefore suppose that *alba* produces male and female ovules in equal numbers. *Alba* ♂ × *dioica* ♀, however, gives nothing but females. Unless, therefore, we assume that there is selective fertilisation we must suppose that all the pollen grains of *alba* carry the female factor—in other words, that so far as the sex factors are concerned there is a difference between the ovules and pollen grains borne by the same plant. Unfortunately further investigation of this case is rendered impossible owing to the complete sterility of the  $F_1$  plants.

That the possibility of a difference between the ovules and pollen grains of the same individual must be taken into account in future work there is evidence from quite a different source. The double stock is an old horticultural favourite, and for centuries it has been known that of itself it sets no seed, but must be raised from special strains of the single variety. "You must understand withall," wrote

John Parkinson of his gilliflowers,<sup>1</sup> "that those plants that beare double flowers, doe beare no seed at all . . . but the onely way to have double flowers any yeare is to save the seedes of those plants of this kinde that beare single flowers, for from that seede will rise, some that will beare single, and some double flowers." With regard to the nature of these

FIG. 44.

Single and double stocks raised from the same single parent.

double-throwing strains of singles, Miss Saunders has recently brought out some interesting facts. She crossed the double-throwing singles with pure singles belonging to strains in which doubles never occur. The cross was made both ways, and in both cases all the  $F_1$  plants were single. A distinction, however, appeared when a further generation

<sup>1</sup> *Paradisus Terrestris*, London, 1629, p. 261.

was raised from the  $F_1$  plants. All the  $F_1$  plants from the pollen of the double-throwing single behaved like double-throwing singles, but of the  $F_1$  plants from the ovules of the double throwers some behaved as double-throwers and some as pure singles. We are led to infer, therefore, that the ovules and pollen grains of the double-throwers, though both produced by the same plant, differ in their relation to the factor (or factors) for doubleness. Doubleness is

apparently carried by all the pollen grains of such plants, but only by some of the ovules. Though the nature of doubleness in stocks is not yet clearly understood, the facts discovered by Miss Saunders suggest strongly that the ovules and pollen grains of the same plant may differ in their transmitting properties, probably owing to some process of segregation in the growing plant which leads to an unequal distribution of some or other factors to the cells which give rise to the ovules as compared with those from which the pollen grains eventually

spring. Whether this may turn out to be the true account or not, the possibility must not be overlooked in future work.

As a third example of an unlooked-for complication, we may recall Mendel's own experiences with the Hawkweeds (*Hieracium*). This genus of plants exhibits an extraordinary profusion of forms differing from one another sometimes in a single feature, sometimes in several. The question as to how far these numerous forms were to be classified as distinct species, how far as varieties, and how far as products of chance hybridisation, was even at that time a source of keen controversy among botanists. There is little doubt that Mendel undertook his experiments on the Hawkweeds in the hope that the conception of unit-characters, so brilliantly demonstrated for the pea, would serve to explain the great profusion of forms among the *Hieraciums*. Owing to the minute size of their florets, these plants offer very considerable technical difficulties in the way of cross-fertilisation. By dint of great perseverance and labour, however, Mendel succeeded in obtaining a few crosses between different forms. These hybrids were reared and a further generation produced from them, and, no doubt somewhat to Mendel's chagrin, every one of them proved to breed true. There was a complete absence of that segregation of characters which he had shown to exist in peas and beans, and had probably looked forward with some confidence to finding in *Hieracium*. More than thirty years passed before the matter was cleared up. To-day we know that the peculiar behaviour of the hybrid *Hieraciums* is due to the fact

that they normally produce seed by a peculiar process of parthenogenesis. It is possible to take an unopened flower and to shear off with a razor all the male organs, together with the stigmata through which the pollen reaches the ovules. The flower, nevertheless, sets perfectly good seed. But the cells from which the seeds develop are not of the same nature as the normal ova of a plant. They are not gametes, but retain the double structure of the maternal cells. They are rather to be regarded as of the nature of buds which early become detached from the parent stock to lead an independent existence, and, like buds, they reproduce exactly the maternal characteristics. The discovery of the true nature of this case was only rendered possible by the development of the study of cytology, and it was not given to Mendel to live long enough to learn why his hybrid *Hieraciums* all bred true.

## CHAPTER XIV

### INTERMEDIATES

So far as we have gone we have found it possible to express the various characters of animals and plants in terms of definite factors which are carried by the gametes, and are distributed according to a definite scheme. Whatever may be the nature of these factors it is possible for purposes of analysis to treat them as indivisible entities which may or may not be present in any given gamete. When the factor is present it is present as a whole. The visible properties, developed by a zygote in the course of its growth, depend upon the nature and variety of the factors carried in by the two gametes which went to its making, and to a less degree upon whether each factor was brought in by both gametes or by one only. If the given factor is brought in by one gamete only, the resulting heterozygote may be more or less intermediate between the homozygous form with a double dose of the factor and the homozygous form which is entirely destitute of the factor. Cases in point are those of the primula flowers and the Andalusian fowls. Nevertheless these intermediates produce only pure gametes as is

shown by the fact that the pure parental types appear in a certain proportion of their offspring. In such cases as these there is but a single type of intermediate, and the simple ratio in which this and the two homozygous forms appear renders the interpretation obvious. But the nature of the  $F_2$  generation may be much more complex and, where we are dealing with factors which interact upon one another, may even present the appearance of a series of intermediate forms, grading from the condition found in one of the original parents to that which occurred in the other. As an illustration we may consider the cross between the Brown Leghorn and Silky fowls which we have already dealt with in connection with the inheritance of sex. The offspring of a Silky hen mated with a Brown Leghorn are in both sexes birds with but a trace of the Silky pigmentation. But when such birds are bred together they produce a generation consisting of chicks as deeply pigmented as the original Silky parent, chicks devoid of pigment like the Brown Leghorn, and chicks in which the pigmentation shows itself in a variety of intermediate stages. Indeed from a hundred chicks bred in this way it would be possible to pick out a number of individuals and arrange them in an apparently continuous series of gradually increasing pigmentation, with the completely unpigmented at one end and the most deeply pigmented at the other. Nevertheless, the case is one in which complete segregation of the different factors takes place, and the apparently continuous series of intermediates is the result of the interaction of the different factors upon one another. The con-

stitution of the  $F_1 \sigma$  is a  $ffPpli$ , and such a bird produces in equal numbers the four sorts of gametes  $fPI$ ,  $fPi$ ,  $fpI$ ,  $fpi$ . The constitution of the  $F_1 \text{♀}$  in this case is  $FfPpli$ . Owing to the repulsion between  $F$  and  $I$  she produces the four kinds of gametes  $FPi$ ,  $Fpi$ ,  $fPI$ ,  $fpI$ , and produces them in equal

$FPi$ $fPI$ ♀	$FPi$ $fPi$ ♀	$FPi$ $fpI$ ♀	$FPi$ $fpi$ ♀
$Fpi$ $fPI$ ♀	$Fpi$ $fPi$ ♀	$Fpi$ $fpI$ ♀	$Fpi$ $fpi$ ♀
$fPI$ $fPI$ ♂	$fPI$ $fPi$ ♂	$fPI$ $fpI$ ♂	$fPI$ $fpi$ ♂
$fpI$ $fPI$ ♂	$fpI$ $fPi$ ♂	$fpI$ $fpI$ ♂	$fpI$ $fpi$ ♂

FIG. 45.

Diagram to illustrate the nature and composition of the  $F_2$  generations arising from the cross of Silky hen with Brown Leghorn cock.

numbers. The result of bringing two such series of gametes together is shown in Fig. 45. Out of the sixteen types of zygote formed, one ( $FfPPIi$ ) is homozygous for the pigmentation factor, and does not contain the inhibitor factor. Such a bird is as deeply pigmented as the pure Silky parent.

Two, again, contain a single dose of  $P$  in the absence of  $I$ . These are nearly as dark as the pure Silky. Four zygotes are destitute of  $P$  though they may or may not contain  $I$ . These birds are completely devoid of pigment like the Brown Leghorn. The remaining nine zygotes show various combinations of the two factors  $P$  and  $I$ , being either  $PPIi$ ,  $PPii$ ,  $PpII$ , or  $Ppli$ , and in each of these cases the pigment is more or less intense according to the constitution of the bird. Thus a bird of the constitution  $PPIi$

approaches in pigmentation a bird of the constitution  $Pp_{ii}$ , while a bird of the constitution  $Pp_{II}$  has but little more pigment than the unpigmented bird. In this way we have seven distinct grades of pigmentation, and the series is further complicated by the fact that these various grades exhibit a rather different amount of pigmentation according as they occur in a male or a female bird, for, generally speaking, the female of a given grade exhibits rather more pigment than the corresponding male. The examination of a number of birds bred in this way might quite well suggest that in this case we were dealing with a character which could break up, as it were, to give a continuous series of intergrading forms between the two extremes. With the constant handling of large numbers it becomes possible to recognise most of the different grades, though even so it is possible to make mistakes. Nevertheless, as breeding tests have amply shown, we are dealing with but two interacting factors which segregate cleanly from one another according to the strict Mendelian rule. The approach to continuity in variation exhibited by the  $F_2$  generation depends upon the fact that these two factors interact upon one another, and to different degrees, according as the zygote is for one or other or both of them in a homozygous or a heterozygous state. Moreover, certain of these intermediates will breed true to an intermediate condition of the pigmentation. A male of the constitution  $ffPPII$  when bred with females of the constitution  $FfPPIi$  will produce only males like itself and females like the maternal parent. We have dealt with this case in some detail, because the existence of families

showing a series of intermediate stages between two characters has sometimes been brought forward in opposition to the view that the characters of organisms depend upon specific factors which are transmitted according to the Mendelian rule. But, as this case from poultry shows clearly, neither the existence of such a continuous series of intermediates, nor the fact that some of them may breed true to the intermediate condition, is incompatible with the Mendelian principle of segregation.

In connection with intermediates a more cogent objection to the Mendelian view is the case of the first cross between two definite varieties thenceforward breeding true. The case that will naturally occur to the reader is that of the mulatto, which results from the cross between the negro and the white. According to general opinion, these mulattos, of intermediate pigmentation, continue to produce mulattos; but when enquiry is pushed to discover the basis upon which general opinion rests, it is found to be nearly always uncritical and vague. Quite recently an attempt to obtain more exact information has been made by Davenport in the United States. From the study of a number of families he came to the conclusion that definite Mendelian segregation occurs. According to him the results can be expressed in terms of two factors, *A* and *B*, either of which, when present, produces the characteristic pigmentation of the skin. Together the two factors produce a darker effect than when only one of them is present. Also, as in the silky fowl, the effect produced by a factor is more marked in the homozygous than in the heterozygous state.

Whether the conclusions will be justified by further investigation, time alone can show. It is, however, clear that the most exact knowledge which we possess at present is in favour of the assumption that Mendelian segregation occurs also in the much-debated case of the mulatto.

Davenport's explanation involves the conception of two independent factors, each sufficient by itself to produce a similar effect, the effect being intensified when both are working together. The idea of a series of similar factors, or **multiple factors** as they are generally termed, owes its origin to Nilsson-Ehle. When investigating the inheritance of red and white colour in the grain of wheat this observer found that, while red was dominant, reds could throw whites in varying proportions. Careful analysis of many such families showed that they fell into three groups, in which the proportion of reds to whites was respectively 3 : 1, 15 : 1, and 63 : 1. These results can be explained on the assumption that there are three independent factors, each of which can produce, independently, the red effect. If we call them *A*, *B*, and *C* we can express the reds which give a 3 : 1 ratio either as *Aabbcc*, *aaBbcc*, or *aabbCc*; the reds which give a 15 : 1 ratio as *AaBbcc*, *AabbCc*, or *aaBbCc*; and the reds which give a 63 : 1 ratio as *AaBbCc*. For a white-grained plant only arises from the union of two gametes *abc*. As the results of a large series of experiments Nilsson-Ehle showed that the conception of multiple factors was in full accordance with the experimental data, and it is now generally accepted by students of genetics. In the case of the wheat grains it cannot be stated

that the depth of the colour is a clear indication of the number of red-producing factors present. Though a plant with all three factors may be of a rather deeper red than one in which but a single factor occurs, the differences in tint are not sufficiently well marked to allow of a colour classification of the reds in terms of their genetic constitution.

Nilsson-Ehle's work, however, placed the conception of multiple factors on a firm basis, and since then it has been applied in explanation of other cases where a long series of intermediates results from a cross. Especially is this the case where quantitative characters such as size and weight are involved. A cross between a large and a dwarf form may sometimes, as in the Cupid sweet-pea, result in complete dominance of the larger form, followed by a simple 3:1 ratio of large to dwarfs in  $F_2$ . But it frequently happens that  $F_1$  is intermediate, and that in  $F_2$  there is a continuous series of forms ranging between the original small and large parents. In illustration we may take a case from poultry, where a cross was made between a Sebright bantam and a Gold-pencilled Hamburgh, the latter breed being normally almost twice as heavy as the former. The  $F_1$  birds were intermediate in size (cf. Fig. 46), though they approximated more closely in this respect to the Hamburgh. The  $F_2$  generation raised from the  $F_1$  birds showed a wide range of variation, at the extremes of which were birds heavier than the Hamburgh, and others lighter than the Sebright. The results obtained are explicable on the view

that four separate factors are concerned, of which each, when present, leads to a definite increase in weight. It must be supposed also that a factor produces a greater effect in the homozygous than in the heterozygous condition. To account for

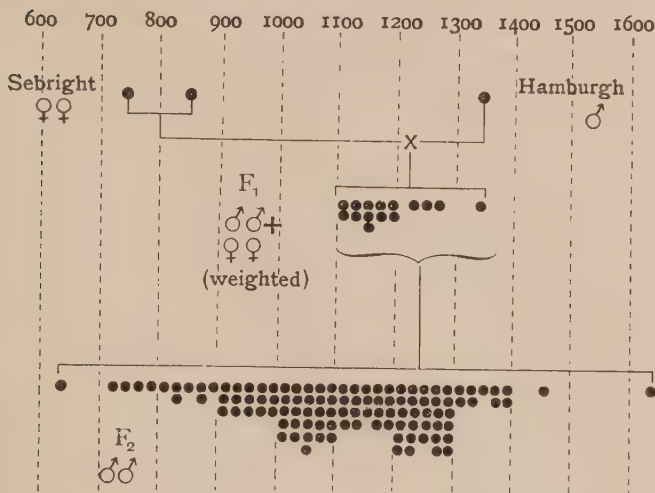

FIG. 46.

Graphic representation of weight distribution in  $F_1$  and  $F_2$  generations from Sebright-Hamburg cross. Each black dot represents an individual, and is placed according to its weight in grams. The weights of the males only are given in  $F_2$ . The weights assigned to the female parents are  $\frac{3}{4}$ ths their actual weights. They have been "weighted" in this way because the normal weight of a hen in these strains is on the average about  $\frac{3}{4}$ ths of the weight of the corresponding cock.

the appearance in  $F_2$  of birds smaller and larger than the original parent breeds, we may suppose that the Hamburg contained three of these four size factors, and that the Sebright contained the other one. Segregation and consequent recombination in  $F_2$  would result in the production of some birds

containing all four factors, *i.e.* the birds larger than the Hamburgh parent ; together with others containing none of the four factors, *i.e.* the birds smaller than the Sebright bantams. It may be added that these very small birds were subsequently mated together and gave only very small offspring like themselves, as indeed they would be expected to do on this hypothesis.

The appearance in  $F_2$  of birds both smaller and larger than the original small and large parents suggests a point of interest. If we denote our four size factors as  $A$ ,  $B$ ,  $C$ , and  $D$ , it is clear that among the many intermediates some, *e.g.*  $AABBccdd$  and  $aabbCCDD$ , should breed true, and at the same time should give, when crossed together,  $F_1$  birds larger than either of the parents. Among the recombinations in  $F_2$  would be some homozygous for all four factors. In other words, from birds of not dissimilar size we should be able to obtain a strain which would breed true to larger size. Such a phenomenon would probably be ascribed by most people to the beneficial effects of a cross, inducing greater vigour in the offspring. But whether this be true or not, we ought not to lose sight of the fact that it may be due, either wholly or in part, to a recombination of multiple factors on the lines suggested by the Sebright-Hamburgh experiments.

Some such process may at times be responsible for the great increase in flower size of which the literature of modern horticulture affords so many examples. Such increase is doubtless often the result of a sudden sport or mutation. There is

historical evidence to show that this is the case in the Chinese Primula as well as in *Primula obconica*. The large flower appeared suddenly, and, as neither species is known to cross with any outside form, it is unlikely to be the result of any recombination of size factors. But there are other species, such as the Daffodils, where hybridisation has been practised with much success. It is not improbable that the gorgeous triumphs of the modern raiser are often due to the aggregation into a single plant of a greater number of size factors than are to be found in any one of the wild or earlier cultivated forms. The Daffodils are promising material for an investigation of this kind, and a properly conducted set of experiments might be expected to yield results of considerable scientific value.

## CHAPTER XV

### VARIATION AND EVOLUTION

THROUGH the facts of heredity we have reached a new conception of the individual. Hitherto we have been accustomed to distinguish between the members of a family of rabbits like that illustrated on Plate I. by assigning to each an individuality, and by making use of certain external features, such as the coat colour or the markings, as convenient outward signs to express our idea that the individuality of these different animals is different. Apart from this, our notions as to what constituted the individuality in each case were at best but vague. Mendelian analysis has placed in our hands a more precise method of estimating and expressing the variations that are to be found between one individual and another. Instead of looking at the individual as a whole, which is in some vague way endowed with an individuality marking it off from its fellows, we now regard it as an organism built up of definite characters superimposed on a basis beyond which for the moment our analysis will not take us. We have begun to realise that each individual has a definite architecture, and that this architecture depends

primarily upon the number and variety of the factors that existed in the two gametes that went to its building. Now most species exhibit considerable variation and exist in a number, often very large, of more or less well-defined varieties. How far can this great variety be explained in terms of a comparatively small number of factors if the number of possible forms depends upon the number of the factors which may be present or absent?

In the simple case where the homozygous and heterozygous conditions are indistinguishable in appearance the number of possible forms is 2, raised to the power of the number of factors concerned. Thus where one factor is concerned there are only  $2^1 = 2$  possible forms, where ten factors are concerned there are  $2^{10} = 1024$  possible forms differing from one another in at most ten and at least one character. Where the factors interact upon one another this number will, of course, be considerably increased. If the heterozygous form is different in appearance from the homozygous form, there are three possible forms connected with each factor; for ten such factors the possible number of individuals would be  $3^{10} = 59,049$ ; for twenty such factors the possible number of different individuals would be  $3^{20} = 3,486,784,401$ . The presence or absence of a comparatively small number of factors in a species carries with it the possibility of an enormous range of individual variation. But every one of these individuals has a perfectly definite constitution which can be determined in each case by the ordinary methods of Mendelian analysis. For in every instance the variation depends upon the

presence or absence of definite factors carried in by the gametes from whose union the individual results. And as these factors separate out cleanly in the gametes which the individual forms, such variations as depend upon them are transmitted strictly according to the Mendelian scheme. Provided that the constitution of the gametes is unchanged, the heredity of such variation is independent of any change in the conditions of nutrition or environment which may operate upon the individual producing the gametes.

But, as everybody knows, an individual organism, whether plant or animal, reacts, and often reacts markedly, to the environmental conditions under which its life is passed. More especially is this to be seen where such characters as size or weight are concerned. More sunlight or a richer soil may mean stronger growth in a plant, better nutrition may result in a finer animal, superior education may lead to a more intelligent man. But although the changed conditions produce a direct effect upon the individual, we have no indisputable evidence that such alterations are connected with alterations in the nature of the gametes which the individual produces. And without this such variations cannot be perpetuated through heredity, but the conditions which produce the effect must always be renewed in each successive generation. We are led, therefore, to the conclusion that two sorts of variations exist, those which are due to the presence of specific factors in the organism, and those which are due to the direct effect of the environment during its lifetime. The former are known as **mutations**, and are inherited according to the Mendelian scheme; the

latter have been termed **fluctuations**, and at present we have no valid reason for supposing that they are ever inherited. For though instances may be found in which effects produced during the lifetime of the individual would appear to affect the offspring, this is not necessarily due to heredity. Thus plants which are poorly nourished, and grown under adverse conditions, may set seed from which come plants that are smaller than the normal, although grown under most favourable conditions. It is natural to attribute the smaller size of the offspring to the conditions under which the parents were grown, and there is no doubt that we should be quite right in doing so. Nevertheless, it need have nothing to do with heredity. As we have already pointed out, the seed is a larval plant which draws its nourishment from the mother. The size of the offspring is affected because the poorly nourished parent offered a bad environment to the young plant, and not because the gametes of the parent were changed through the adverse conditions under which it grew. The parent in this case is not only the producer of gametes, but also a part of the environment of the young plant, and it is in this latter capacity that it affects its offspring. Wherever, as in plants and mammals, the organism is parasitic upon the mother during its earlier stages, the state of nutrition of the latter will almost certainly react upon it, and in this way a semblance of transmitted weakness or vigour is brought about. Such a connection between mother and offspring is purely one of environment, and it cannot be too strongly emphasised that it has nothing to do with the ordinary process of heredity.

The distinction between these two kinds of variation, so entirely different in their causation, renders it possible to obtain a clearer view of the process of evolution than that recently prevalent. As Darwin long ago realised, any theory of evolution must be based upon the facts of heredity and variation. Evolution only comes about through the survival of certain variations and the elimination of others. But to be of any moment in evolutionary change a variation must be inherited. And to be inherited it must be represented in the gametes. This, as we have seen, is the case for those variations which we have termed mutations. For the inheritance of fluctuations, on the other hand, of the variations which result from the direct action of the environment upon the individual, there is no indisputable evidence. Consequently we have no reason for regarding them as playing any part in the production of that succession of temporarily stable forms which we term evolution. In the light of our present knowledge we must regard the mutation as the basis of evolution—as the material upon which natural selection works. For it is the only form of variation of whose heredity we have any certain knowledge.

It is evident that this view of the process of evolution is in some respects at variance with that generally held during the past half century. There we were given the conception of an abstract type representing the species, and from it most of the individuals diverged in various directions, though, generally speaking, only to a very small extent. It was assumed that any variation, however small, might have a selection value, that is to say, could be

transmitted to the offspring. Some of these would possess it in a less and some in a greater degree than the parent. If the variation were a useful one, those possessing to a rather greater extent would be favoured through the action of natural selection at the expense of their less fortunate brethren, and would leave a greater number of offspring, of whom some possessed it in an even more marked degree than themselves. And so it would go on. The process was a cumulative one. The slightest variation in a favourable direction gave natural selection a starting-point to work on. Through the continued action of natural selection on each successive generation the useful variation was gradually worked up, until at last it reached the magnitude of a specific distinction. Were it possible in such a case to have all the forms before us, they would present the appearance of a long series imperceptibly grading from one extreme to the other.

Upon this view are made two assumptions not unnatural in the absence of any exact knowledge of the nature of heredity and variation. It was assumed, in the first place, that variation was a continuous process, and, second, that any variation could be transmitted to the offspring. Both of these assumptions have since been shown to be unjustified. Even before Mendel's work became known Bateson had begun to call attention to the prevalence of discontinuity in variation, and a few years later this was emphasised by the Dutch botanist Hugo de Vries in his great work on *The Mutation Theory*. The ferment of new ideas was already working in the solution, and under the stimulus of Mendel's

work they have rapidly crystallised out. With the advent of heredity as a definite science we have been led to revise our views as to the nature of variation, and consequently, in some respects, as to the trend of evolution. Heritable variation has a definite basis in the gamete, and it is to the gamete, therefore, not to the individual, that we must look for the initiation of this process. Somewhere or other in the course of their production is added or removed the factor upon whose removal or addition the new variation owes its existence. The new variation springs into being by a sudden step, not by a process of gradual and almost imperceptible augmentation. It is not continuous, but discontinuous, because it is based upon the presence or absence of some definite factor or factors—upon discontinuity in the gametes from which it sprang. Once formed, its continued existence is subject to the arbitrament of natural selection. If of value in the struggle for existence natural selection will decide that those who possess it shall have a better chance of survival and of leaving offspring than those who do not possess it. If it is harmful to the individual natural selection will soon bring about its elimination. But if the new variation is neither harmful nor useful there seems no reason why it should not persist.

In this way we avoid a difficulty which beset the older view. For on that view no new character could be developed except by the piling up of minute variations through the action of natural selection. Consequently any character found in animals and plants must be supposed to be of

some definite use to the individual. Otherwise it could not have developed through the action of natural selection. But there are plenty of characters to which it is exceedingly difficult to ascribe any utility, and the ingenuity of the supporters of this view has often been severely taxed to account for their existence. On the more modern view this difficulty is avoided. The origin of a new variation is independent of natural selection, and provided that it is not directly harmful there is no reason why it should not persist. In this way we are released from the burden of discovering a utilitarian motive behind all the multitudinous characters of living organisms. For we now recognise that the function of natural selection is selection, and not creation. It has nothing to do with the formation of the new variation. It merely decides whether it is to survive or to be eliminated.

One of the arguments made use of by supporters of the older view is that drawn from the study of adaptation. Animals and plants are as a rule remarkably well adapted to living the life which their surroundings impose upon them, and in some cases this adaptation is exceedingly striking. Especially is this so in the many instances of what is called protective coloration, where the animal comes to resemble its surroundings so closely that it may reasonably be supposed to cheat even the keenest sighted enemy. Surely, we are told, such perfect adaptation could hardly have arisen through the mere survival of chance sports. Surely there must be some guiding hand moulding the species into the required shape. The argument is an old one. For

John Ray that guiding hand was the superior wisdom of the Creator: for the modern Darwinian it is Natural Selection controlling the direction of variation. Mendelism certainly offers no suggestion of any such controlling force. It interprets the variations of living forms in terms of definite physiological factors, and the diversity of animal and plant life is due to the gain or loss of these factors, to the origination of new ones, or to fresh combinations among those already in existence. Nor is there any valid reason against the supposition that even the most remarkable cases of resemblance, such as that of the leaf insect, may have arisen through a process of mutation. Experience with domestic plants and animals shows that the most bizarre forms may arise as sports and perpetuate themselves. Were such forms, arising under natural conditions, to be favoured by natural selection owing to a resemblance to something in their environment, we should obtain a striking case of protective adaptation. And here it must not be forgotten that those striking cases to which our attention is generally called are but a very small minority of the existing forms of life.

For that special group of adaptation phenomena classed under the head of Mimicry, Mendelism seems to offer an interpretation simpler than that at present in vogue. This perhaps may be more clearly expressed by taking a specific case. There is in Africa a genus of Danaine butterflies known as *Amauris*, and there are reasons for considering that the group to which it belongs possesses properties which render it unpalatable to vertebrate enemies such as birds or monkeys. In the same region is also found the

PLATE VII.

*Euralia mima*

*Euralia wahlbergi*

*Amauris echeria*

*Amauris dominicanus*

genus *Euralia* belonging to the entirely different family of the Nymphalidae, to which there is no evidence for assigning the disagreeable properties of the Danaines. Now the different species of *Euralia* show remarkably close resemblances to the species of *Amauris*, which are found flying in the same region, and it is supposed that by "mimicking" the unpalatable forms they impose upon their enemies and thereby acquire immunity from attack. The point at issue is the way in which this seemingly purposeful resemblance has been brought about.

One of the species of *Euralia* occurs in two very distinct forms (Pl. VII.) which were previously regarded as separate species under the names *E. wahlbergi* and *E. mima*. These two forms respectively resemble *Amauris dominicanus* and *A. echeria*. For purposes of argument we will assume that one of these forms has been derived from the other and that *A. dominicanus* is the more recent form of the two. On the modern Darwinian view certain individuals of *A. echeria* gradually diverged from the *echeria* type and eventually reached the *dominicanus* type, though why this should have happened does not appear to be clear. At the same time those specimens of the *Euralia* which tended to vary in the direction of *A. dominicanus* in places where this species was more abundant than *A. echeria* were encouraged by natural selection, and under its guiding hand the form *wahlbergi* eventually arose from *mima*.

According to Mendelian views, on the other hand, the *dominicanus* pattern arose suddenly from the *echeria* pattern (or *vice versa*), and similarly *wahlbergi* arose suddenly from *mima*. If *wahlbergi*

occurred where *A. dominicanus* was common and *A. echeria* was rare, its resemblance to the more plentiful distasteful form would give it the advantage over *mima* and allow it to establish itself in place of the latter. On the modern Darwinian view natural selection gradually shapes *mima* into the *wahlbergi* form owing to the presence of *A. dominicanus*; on the Mendelian view natural selection merely conserves the *wahlbergi* form when once it has arisen. Now this case of mimicry is one of especial interest, because we have experimental evidence that the relation between *mima* and *wahlbergi* is a simple Mendelian one, *mima* here being the dominant and *wahlbergi* the recessive form. The two have been proved to occur in families bred from the same female without the occurrence of any intermediates, and the fact that the two segregate cleanly is strong evidence in favour of the Mendelian view. On this view the genera *Amauris* and *Euralia* contain a similar set of pattern factors, and the conditions, whatever they may be, which bring about mutation in the former lead to the production of a similar mutation in the latter. Of the different forms of *Euralia* produced in any region that one has the best chance of survival, through the operation of natural selection, which resembles the most plentiful *Amauris* form. Mimetic resemblance is a true phenomenon, but natural selection plays the part of a conservative, not of a formative agent.<sup>1</sup>

<sup>1</sup> The reader who is interested in this subject will find it discussed more fully in my book on *Mimicry in Butterflies*. Cambridge University Press, 1915.

It is interesting to recall that in earlier years Darwin was inclined to ascribe more importance to "sports" as opposed to continuous minute variation, and to consider that they might play a not inconsiderable part in the formation of new varieties in nature. This view, however, he gave up later, because he thought that the relatively rare sport, or mutation, would rapidly disappear through the swamping effects of crossing with the more abundant normal form, and so, even though favoured by natural selection, would never succeed in establishing itself. Mendel's discovery has eliminated this difficulty. For suppose that the sport differed from the normal in the loss of a factor and were recessive. When mated with the normal this character would seem to disappear, though, of course, half of the gametes of its progeny would bear it. By continual crossing with normals a small proportion of heterozygotes would eventually be scattered among the population, and as soon as any two of these mated together the recessive sport would appear in one quarter of their offspring.

A suggestive contribution to this subject was recently made by G. H. Hardy. Considering the distribution of a single factor in a mixed population consisting of the heterozygous and the two homozygous forms, he showed that such a population, breeding at random, rapidly fell into a stable condition with regard to the proportion of these three forms, whatever may have been the proportion of the three forms to start with. Let us suppose, for instance, that the population consists of  $p$  homozygotes of one kind,  $r$  homozygotes of the other kind, and

$2q$  heterozygotes. Hardy pointed out that, other things being equal, such a population would be in equilibrium for this particular factor so long as the condition  $q^2 = pr$  was fulfilled. If the condition is fulfilled to start with the population remains in equilibrium. If the condition is not fulfilled to start with, Hardy showed that a position of equilibrium becomes established after a single generation, and that this position is thereafter maintained. The proportions of the three classes which satisfy the equation  $q^2 = pr$  are exceedingly numerous, and populations in which they existed in the proportions shown in the appended table would remain in stable equilibrium generation after generation :

$p$ .	$2q$ .	$r$ .
1	2	1
1	4	4
1	6	9
1	8	16
1	20,000	100,000,000
1	$2n$	$n^2$

This, of course, assumes that all three classes are equally fertile, and that no form of selection is taking place to the benefit of one class more than of another. Moreover, it makes no difference whether  $p$  represents the homozygous dominants or whether it stands for the recessives. A population containing a very small proportion of dominants, and one containing a similar proportion of recessives, are equally stable. The term dominant is in some respects apt to be misleading, for a dominant character cannot in virtue of its dominance establish itself at the expense of a recessive one. Brown

eyes in man are dominant to blue, but there is no reason to suppose that as years go on the population of these islands will become increasingly brown-eyed. Given equality of conditions both are on an equal footing. If, however, either dominant or recessive be favoured by selection the conditions are altered, and it can be shown that even a small advantage possessed by the one will rapidly lead to the elimination of the other. Even with but a 5 per cent selection advantage in its favour it can be shown that a rare sport will oust the normal form in a few hundred generations. In this way we are freed from a difficulty inherent in the older view that varieties arose through a long-continued process involving the accumulation of very slight variations. On that view the establishing of a new type was of necessity a very long and tedious business, involving many thousands of generations. For this reason the biologist has been accustomed to demand a very large supply of time, often a great deal more than the physicist is disposed to grant, and this has sometimes led him to expostulate with the latter for cutting off the supply. On the newer views, however, this difficulty need not arise, for we realise that the origin and establishing of a new form may be a very much more rapid process than has hitherto been deemed possible.

One last question with regard to evolution. How far does Mendelism help us in connection with the problem of the origin of species? Among the plants and animals with which we have dealt we have been able to show that distinct differences, often considerable, in colour, size, and structure, may be interpreted in terms of Mendelian factors. It is not

unlikely that most of the various characters which the systematist uses to mark off one species from another, the so-called specific characters, are of this nature. They serve as convenient labels, but are not essential to the conception of species. A systematist who defined the wild sweet pea could hardly fail to include in his definition such characters as the procumbent habit, the tendrils, the form of the pollen, the shape of the flower, and its purple colour. Yet all these and other characters have been proved to depend upon the presence of definite factors which can be removed by appropriate crossing. By this means we can produce a small plant a few inches in height with an erect habit of growth, without tendrils, with round instead of oblong pollen, and with colourless deformed flowers quite different in appearance from those of the wild form. Such a plant would breed perfectly true, and a botanist to whom it was presented, if ignorant of its origin, might easily relegate it to a different genus. Nevertheless, though so widely divergent in structure, such a plant must yet be regarded as belonging to the species *Lathyrus odoratus*. For it still remains fertile with the many different varieties of sweet-pea. It is not visible attributes that constitute the essential difference between one species and another. The essential difference, whatever it may be, is that underlying the phenomenon of sterility. The visible attributes are those made use of by the systematist in cataloguing the different forms of animal and plant life, for he has no other choice. But it must not be forgotten that they are often misleading. Until they were bred together *Euralia wahlbergi*

and *E. mima* were regarded as perfectly valid species, and there is little doubt that numbers of recognised species will eventually fall to the ground in the same way as soon as we are in a position to apply the test of breeding. Mendelism has helped us to realise that specific characters may be but incidental to a species—that the true criterion of what constitutes a species is sterility, and that particular form of sterility which prevents two healthy gametes on uniting from producing a zygote with normal powers of growth and reproduction. For there are forms of sterility which are purely mechanical. The pollen of *Mirabilis jalapa* cannot fertilise *M. longiflora*, because the pollen tubes of the former are not long enough to penetrate down to the ovules of the latter. Hybrids can nevertheless be obtained from the reciprocal cross. Nor should we expect offspring from a St. Bernard and a toy terrier without recourse to artificial fertilisation. Or sterility may be due to pathological causes which prevent the gametes from meeting one another in a healthy state. But in most cases it is probable that the sterility is due to some other cause. It is not inconceivable that definite differences in chemical composition render the protoplasm of one species toxic to the gametes of the other, and if this is so it is not impossible that we may some day be able to express these differences in terms of Mendelian factors. The very nature of the case makes it one of extreme difficulty for experimental investigation. At any rate, we realise more clearly than before that the problem of species is not one that can be resolved by the study of morphology or of systematics. It is a problem in physiology.

## CHAPTER XVI

### ECONOMICAL

SINCE heredity lies at the basis of the breeder's work, it is evident that any contribution to a more exact knowledge of this subject must prove of service to him, and there is no doubt that he will be able to profit by Mendelian knowledge in the conduct of his operations. Indeed, as we shall see later, these ideas have already led to striking results in the raising of new and more profitable varieties. In the first place, heredity is a question of individuals. Identity of appearance is no sure guide to reproductive qualities. Two individuals similarly bred and indistinguishable in outward form may nevertheless behave entirely differently when bred from. Take, for instance, the family of sweet-peas shown on Plate IV. The  $F_2$  generation here consists of seven distinct types, three sorts of purples, three sorts of reds, and whites. Let us suppose that our object is to obtain a true breeding strain of the pale purple picotee form. Now from the proportions in which they come we know that the dilute colour is due to the absence of the factor which intensifies the colour. Consequently the

picotee cannot throw the two deeper shades of red or purple. But it may be heterozygous for the purpling factor, when it will throw the dilute red (Tinged white), or it may be heterozygous for either or both of the two colour factors (cf. p. 41), in which case it will throw whites. Of the picotees which come in such a family, therefore, some will give picotees, tinged whites, and whites, others will give picotees and tinged whites only, others will give picotees and whites only, while others, again, and these the least numerous, will give nothing but picotees. The new variety is already fixed in a certain definite proportion of the plants; in this particular instance in 1 out of every 27. All that remains to be done is to pick out these plants. Since all the picotees look alike, whatever their breeding capacity, the only way to do this is to save the seed from a number of such plants *individually*, and to raise a further generation. Some of them will be found to breed true. The variety is then established, and may at once be put on the market with full confidence that it will hereafter throw none of the other forms. The all-important thing is to save and sow the seed of separate individuals separately. However alike they look, the seed from different individuals must on no account be mixed. Provided that due care is taken in this respect no long and tedious process of selection is required for the fixation of any given variety. Every possible variety arising from a cross appears in the  $F_2$  generation if only a sufficient number is raised, and of all these different varieties a certain proportion of each is already fixed. Heredity is a question of

individuals, and the recognition of this will save the breeder much labour, and enable him to fix his varieties in the shortest possible time.

Such cases as these of the sweet-pea throw a fresh light upon another of the breeder's conceptions, that of purity of type. Hitherto the criterion of a "pure-bred" thing, whether plant or animal, has been its pedigree, and the individual was regarded as more or less pure bred for a given quality according as it could show a longer or shorter list of ancestors possessing this quality. To-day we realise that this is not essential. The pure-bred picotee appears in our  $F_2$  family though its parent was a purple bicolor, and its remoter ancestors whites for generations. So also from the cross between pure strains of black and albino rabbits we may obtain in the  $F_2$  generation animals of the wild agouti colour which breed as true to type as the pure wild rabbit of irreproachable pedigree. The true test of the pure breeding thing lies not in its ancestry but in the nature of the gametes which have gone to its making. Whenever two similarly constituted gametes unite, whatever the nature of the parents from which they arose, the resulting individual is homozygous in all respects and must consequently breed true. In deciding questions of purity it is to the gamete, and not to ancestry, that our appeal must henceforth be made.

Improvement is after all the keynote to the breeder's operations. He is aiming at the production of a strain which shall combine the greatest number of desirable properties with the least number of undesirable ones. This good quality he must

take from one strain, that from another, and that, again, from a third, while at the same time avoiding all the poor qualities that these different strains possess. It is evident that the Mendelian conception of characters based upon definite factors which are transmitted on a definite scheme must prove of the greatest service to him. For once these factors have been determined their distribution is brought under control, and they can be associated together or dissociated at the breeder's will. The chief labour involved is that necessary for the determination of the factors upon which the various characters depend. For it often happens that what appears to be a simple character turns out when analysed to depend upon the simultaneous presence of several distinct factors. Thus the Malay fowl breeds true to the walnut comb, as does also the Leghorn to the single comb, and when pure strains are crossed all the offspring have walnut combs. At first sight it would be not unnatural to regard the difference as dependent upon the presence or absence of a single factor. Yet, as we have already seen, two other types of comb, the pea and the rose, make their appearance in the  $F_2$  generation. Analysis shows that the difference between the walnut and the single is a difference of two factors, and it is not until this has been determined that we can proceed with certainty to transfer the walnut character to a single-combed breed. Moreover, in his process of analysis the breeder must be prepared to encounter the various phenomena that we have described under the headings of interaction of factors, coupling, and repulsion, and the recognition of these phenomena

will naturally influence his procedure. Or, again, his experiments may show him that one of the characters he wants, like the blue of the Andalusian fowl, is dependent upon the heterozygous nature of the individual which exhibits it, and if such is the case he will be wise to refrain from any futile attempt at fixing it. If it is essential, it must be built up again in each generation, and he will recognise that the most economical way of doing this is to cross the two pure strains so that all the offspring may possess the desired character. The labour of analysis is often an intricate and tedious business. But once done it is done once for all. As soon as the various factors are determined upon which the various characters of the individual depend, as soon as the material to be made use of has been properly analysed, the production and fixation of the required combinations becomes a matter of simple detail.

An excellent example of the practical application of Mendelian principles is afforded by the experiments which Professor Biffen has recently carried out in Cambridge. Taken as a whole English wheats compare favourably with foreign ones in respect of their cropping power. On the other hand, they have two serious defects. They are liable to suffer from the attacks of the fungus which causes rust, and they do not bake into a good loaf. This last property depends upon the amount of gluten present, and it is the greater proportion of this which gives to the "hard" foreign wheat its quality of causing the loaf to rise well when baked. For some time it was held that "hard" wheat with

a high glutinous content could not be grown in the English climate, and undoubtedly most of the hard varieties imported for trial deteriorated greatly in a very short time. Professor Biffen managed to obtain a hard wheat which kept its qualities when grown in England. But in spite of the superior quality of its grain from the baker's point of view, its cropping capacity was too low for it to be grown profitably in competition with English wheats. Like the latter, it was also subject to rust. Among the many varieties which Professor Biffen collected and grew for observation he managed to find one which was completely immune to the attacks of the rust fungus, though in other respects it had no desirable quality to recommend it. Now as the result of an elaborate series of investigations he was able to show that the qualities of heavy cropping capacity, "hardness" of grain, and immunity to rust can all be expressed in terms of Mendelian factors. Having once analysed his material the rest was comparatively simple, and in a few years he has been able to build up a strain of wheat which combines the cropping capacity of the best English varieties with the hardness of the foreign kinds, and at the same time is completely immune to rust. This wheat has already been shown to keep its qualities unchanged for several years, and there is little doubt that when it comes to be grown in quantity it will exert an appreciable influence on wheat-growing in Great Britain.

It may be objected that it is often with small differences rather than with the larger and more striking ones that the breeder is mainly concerned.

It does not matter much to him whether the colour of a pea flower is purple or pink or white. But it does matter whether the plant bears rather larger seeds than usual, or rather more of them. Even a small difference when multiplied by the size of the crop will effect a considerable difference in the profit. It is the general experience of seedsmen and others that differences of this nature are often capable of being developed up to a certain point by a process

FIG. 47.

Curves to illustrate the influence of selection.

of careful selection each generation. At first sight this appears to be something very like the gradual accumulation of minute variations through the continuous application of a selective process. Some recent experiments by Professor Johannsen of Copenhagen set the matter in a different light. One of his investigations deals with the inheritance of the weight of beans, but as an account of these experiments would involve us in the consideration of a large amount of detail we may take a simple imaginary case to illustrate the nature of the con-

clusions at which he arrived. If we weigh a number of seeds collected from a patch of plants such as Johannsen's beans we should find that they varied considerably in size. The majority would probably not diverge very greatly from the general average, and as we approached the high or low extreme we should find a constantly decreasing number of individuals with these weights. Let us suppose that the weight of our seed varied between 4 and 20 grains, that the greatest number of seeds were of the mean weight, viz. 12 grains, and that as we passed to either extreme at 4 and 20 the number became regularly less. The weight relation of such a collection of seeds can be expressed by the accompanying curve (Fig. 47). Now if we select for sowing only that seed which weighs over 12 grains we shall find that in the next generation the average weight of the seed is raised and the curve becomes somewhat shifted to the right as in the dotted line of Fig. 47. By continually selecting we can shift our curve a little more to the right, *i.e.* we can increase the average weight of the seeds until at last we come to a limit beyond which further selection has no effect. This phenomenon has been long known, and it was customary to regard these variations as of a continuous nature, *i.e.* as all chance fluctuations in a homogeneous mass, and the effect of selection was supposed to afford evidence that small continuous variations could be increased by this process. But Johannsen's results point to another interpretation. Instead of our material being homogeneous it is probably a mixture of several strains each with its

own average weight about which the varying conditions of the environment cause it to fluctuate. Each of these strains is termed a **pure line**. If we imagine that there are three such pure lines in our imaginary case, with average weights 10, 12, 14 grains respectively, and if the range of fluctuation of each of these pure lines is 12 grains, then our

FIG. 48.

Curves to illustrate the conception of pure lines in a population.

curve must be represented as made up of the three components

A	fluctuating	between	4	and	16	with	a	mean	of	10
B	"	"	6	"	18	"	"	"	"	12
C	"	"	8	"	20	"	"	"	"	14

as is shown in Fig. 48. A seed that weighs 12 grains may belong to any of these three strains. It may be an average seed of B, or a rather large seed of A, or a rather small seed of C. If it belongs to B its offspring will average 12 grains, if to A they will average 10 grains, and if to C they will average 14 grains. Seeds of similar weight may give a different result because they happen to

be fluctuations of different pure lines. But within the pure line any seed, large or small, produces the average result for that line. Thus a seed of line C which weighs 20 grains will give practically the same result as one that weighs 10 grains.

On this view we can understand why selection of the largest seed raises the average weight in the next generation. We are picking out more of C and less of A and B, and as this process is repeated the proportion of C gradually increases and we get the appearance of selection acting on a continuously varying homogeneous material and producing a permanent effect. This is because the interval between the average weight of the different pure lines is small compared with the environmental fluctuations. None the less it is there, and the secret of separating and fixing any of these pure lines is again to breed from the individual separately. As soon as the pure line is separated further selection becomes superfluous.

Since the publication of Darwin's famous work upon the effects of cross- and self-fertilisation it has been generally accepted that the effect of a cross is commonly, though not always, to introduce fresh vigour into the offspring, though why this should be so we are quite at a loss to explain.<sup>1</sup> Continued close inbreeding, on the contrary, eventually leads to deterioration, though, as in many self-fertilised plants, a considerable number of generations may elapse before it shows itself in any marked degree. The fine quality of many of the seedsman's choice varieties of vegetables probably depends upon the

<sup>1</sup> But see p. 166.

fact that they have resulted from a cross but a few generations back, and it is possible that they often oust the older kinds, not because they started as something intrinsically better, but because the latter had gradually deteriorated through continuous self-fertilisation. Most breeders are fully alive to the beneficial results of a cross so far as vigour is concerned, but they often hesitate to embark upon it owing to what was held to be the inevitably lengthy and laborious business of recovering the original variety and refixing it, even if in the process it was not altogether lost. That danger Mendelism has removed, and we now know that by working on these lines it is possible in three or four generations to recover the original variety in a fixed state with all the superadded vigour that follows from a cross.

Nor is the problem one that concerns self-fertilised plants only. Plants that are reproduced asexually often appear to deteriorate after a few generations unless a sexual generation is introduced. New varieties of potato, for example, are frequently put upon the market, and their excellent qualities give them a considerable vogue. Much is expected of them, but time after time they deteriorate in a disappointing way and are lost to sight. It is not improbable that we are here concerned with a case in which the plants lose their vigour after a few asexual generations of reproduction from tubers, and can only recover it with the stimulus that results from the interpolation of a sexual generation. Unfortunately this generally means that the variety is lost, for owing to the haphazard way in which new kinds of potatoes are reproduced it is probable that

most cultivated varieties are complex heterozygotes. Were the potato plant subjected to careful analysis and the various factors determined upon which its variations depend, we should be in a position to remake continually any good potato without running the risk of losing it altogether, as is now so often the case.

The application of Mendelian principles is likely to prove of more immediate service for plants than animals, for owing to the large numbers which can be rapidly raised from a single individual and the prevalence of self-fertilisation, the process of analysis is greatly simplified. Even apart from the circumstance that the two sexes may sometimes differ in their powers of transmission, the mere fact of their separation renders the analysis of their properties more difficult. And as the constitution of the individual is determined by the nature and quality of its offspring, it is not easy to obtain this knowledge where the offspring, as in most animals, are relatively few. Still, as has been abundantly shown, the same principles hold good here also, and there is no reason why the process of analysis, though more troublesome, should not be effectively carried out. At the same time, it affords the breeder a rational basis for some familiar but puzzling phenomena. The fact, for instance, that certain characters often "skip a generation" is simply the effect of dominance in  $F_1$  and the reappearance of the recessive character in the following generation. "Reversion" and "atavism," again, are phenomena which are no longer mysterious, but can be simply expressed in Mendelian terms as we have already suggested in Chap. VI. The

occasional appearance of a sport in a supposedly pure strain is often due to the reappearance of a recessive character. Thus even in the most highly pedigreed strains of polled cattle such as the Aberdeen-Angus, occasional individuals with horns appear. The polled character is dominant to the horned, and the occasional reappearance of the horned animal is due to the fact that some of the polled herd are heterozygous in this character. When two such individuals are mated, the chances are 1 in 4 that the offspring will be horned. Though the heterozygous individuals may be indistinguishable in appearance from the pure dominant, they can be readily separated by the breeding test. For when crossed by the recessive, in this case horned animals, the pure dominant gives only polled beasts, while the heterozygous individual gives equal numbers of polled and horned ones. In this particular instance it would probably be impracticable to test all the cows by crossing with a horned bull. For in each case it would be necessary to have several polled calves from each before they could with reasonable certainty be regarded as pure dominants. But to ensure that no horned calves should come, it is enough to use a bull which is pure for that character. This can easily be tested by crossing him with a dozen or so horned cows. If he gets no horned calves out of these he may be regarded as a pure dominant and thenceforward put to his own cows, whether horned or polled, with the certainty that all his calves will be polled.

Or, again, suppose that a breeder has a chestnut mare and wishes to make certain of a bay foal from

her. We know that bay is dominant to chestnut, and that if a homozygous bay stallion is used a bay foal must result. In his choice of a sire, therefore, the breeder must be guided by the previous record of the animal, and select one that has never given anything but bays when put to either bay or chestnut mares. In this way he will assure himself of a bay foal from his chestnut mare, whereas if the record of the sire shows that he has given chestnuts he will be heterozygous, and the chances of his getting a bay or a chestnut out of a chestnut mare are equal.

It is not impossible that the breeder may be unwilling to test his animals by crossing them with a different breed, through fear that their purity may be thereby impaired, and that the influence of the previous cross may show itself in succeeding generations. He might hesitate, for instance, to test his polled cows by crossing them with a horned bull, for fear of getting horned calves when the cows were afterwards put to a polled bull of their own breed. The belief in the power of a sire to influence subsequent generations, or telegony as it is sometimes called, is not uncommon even to-day. Nevertheless, carefully conducted experiments by more than one competent observer have failed to elicit a single shred of unequivocal evidence in favour of the view. Until we have evidence based upon experiments which are capable of repetition, we may safely ignore telegony as a factor in heredity.

Heterozygous forms play a greater part in the breeding of animals than of plants, for many of the qualities sought after by the breeder are of this nature. Such is the blue of the Andalusian fowl,

and, according to Professor Wilson, the roan of the Shorthorn is similar, being the heterozygous form produced by mating red with white. The characters of certain breeds of canaries and pigeons again appear to depend upon their heterozygous nature. Such forms cannot, of course, ever be bred true, and where several factors are concerned they may when bred together produce but a small proportion of offspring like themselves. As soon, however, as their constitution has been analysed and expressed in terms of Mendelian factors, pure strains can be built up which when crossed will give nothing but offspring of the desired heterozygous form.

The points with which the breeder is concerned are often fine ones, not very evident except to the practised eye. Between an ordinary Dutch rabbit and a winner, or between the comb of a Hamburgh that is fit to show and one that is not, the differences are not very apparent to the uninitiated. Whether Mendelism will assist the breeder in the production of these finer points is at present doubtful. It may be that these small differences are heritable, such as those that form the basis of Johannsen's pure lines. In this case the breeder's outlook is hopeful. But it may be that the variations which he seeks to perpetuate are of the nature of fluctuations, dependent upon the earlier life conditions of the individual, and not upon the constitution of the gametes by which it was formed. If such is the case, he will get no help from the science of heredity, for we know of no evidence which might lead us to suppose that variations of this sort can ever become fixed and heritable.

## CHAPTER XVII

### MAN

THOUGH the interest attaching to heredity in man is more widespread than in other animals, it is far more difficult to obtain evidence that is both complete and accurate. The species is one in which the differentiating characters separating individual from individual are very numerous, while the number of the offspring is comparatively few, and the generations are far between. For these reasons, even if it were possible, direct experimental work with man would be likely to prove both tedious and expensive. There is, however, another method besides the direct one from which something can be learned. This consists in collecting all the evidence possible, arranging it in the form of pedigrees, and comparing it with standard cases already worked out in animals and plants. In this way it has been possible to demonstrate in man the existence of several characters showing simple Mendelian inheritance. As few besides medical men have hitherto been concerned practically with heredity, such records as exist are, for the most part, records of deformity or of disease. So it happens that most of the pedigrees

at present available deal with characters which are usually classed as abnormal. In some of these the inheritance is clearly Mendelian. One of the cases

FIG. 49.

Normal and brachydactylous hands placed together for comparison.  
(From Drinkwater.)

which has been most fully worked out is that of a deformity known as brachydactyly. In brachydactylous people the whole of the body is much stunted, and the fingers and toes appear to have two joints only instead of three (cf. Figs. 49 and 50).

The inheritance of this peculiarity has been carefully investigated by Dr. Drinkwater, who collected all the data he was able to find among the members of a large family in which it occurred. The result is the pedigree shown on p. 202. It is assumed that all who are recorded as having offspring were married to normals. Examination of the pedigree brings out the facts (1) that all affected individuals have an affected parent; (2) that none of the unaffected in-

FIG. 50.

Radiograph of a brachydactylous hand.

dividuals, though sprung from the affected, ever have descendants who are affected; and (3) that in families where both affected and unaffected occur, the numbers of the two classes are, on the average, equal. (The sum of such families in the complete pedigree is thirty-nine affected and thirty-six normals.) It is obvious that these are the conditions which are fulfilled in a simple Mendelian case, and there is nothing in this pedigree to contradict the assertion that brachydactyly, whatever it may be due to,

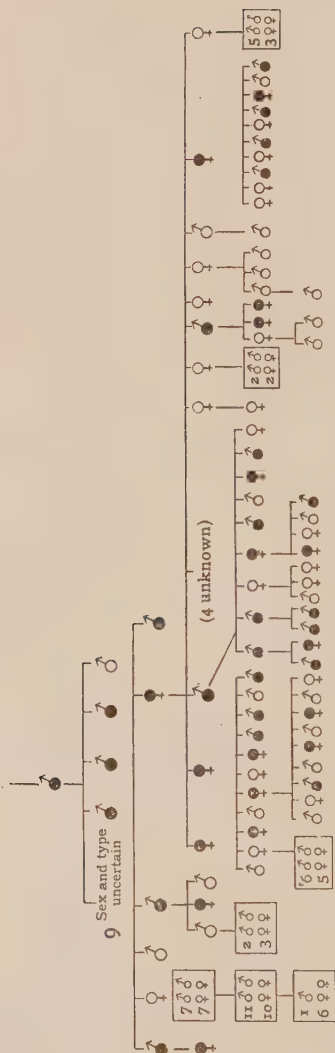

FIG. 51.

Pedigree of Drinkwater's brachydactylous family.

The affected members are indicated by black and the normals by light circles.

behaves as a simple dominant to the normal form, *i.e.* that it depends upon a factor which the normal does not contain. The recessive normals cannot transmit the affected condition whatever their ancestry. Once free they are always free, and can marry other normals with full confidence that none of their children will show the deformity.

The evidence available from pedigrees has revealed the simplest form of Mendelian inheritance in several human defects and diseases, among which may be mentioned presenile cataract of the eyes, an abnormal form of skin thickening in the palms of the hands and soles of the feet, known as tylosis, and epidermolysis bullosa, a disease in which the skin rises up into numerous bursting blisters.

Among the most interesting of all human pedigrees is one recently built up by Mr. Nettleship from the records of a night-blind family living near Montpellier in the south of France. In night-blind people the retina is insensitive to light which falls below a certain intensity, and such people are consequently blind in failing daylight or in moonlight. As the Montpellier case had excited interest for some time, the records are unusually complete. They commence with a certain Jean Nougaret, who was born in 1637, and suffered from night-blindness, and they end for the present with children who are to-day but a few years of age. Particulars are known of over 2000 of the descendants of Jean Nougaret. Through ten generations and nearly three centuries the affection has behaved as a Mendelian dominant, and there is no sign that long-continued marriage with folk of normal vision has produced any amelioration of the night-blind state.

Besides cases such as these where a simple form of Mendelian inheritance is obviously indicated, there are others which are more difficult to read. Of some it may be said that on the whole the peculiarity behaves as though it were an ordinary dominant; but that exceptions occur in which affected children are born to unaffected parents. It is not impossible that the condition may, like colour in the sweet-pea, depend upon the presence or absence of more than one factor. In none of these cases, however, are the data sufficient for determining with certainty whether this is so or not.

A group of cases of exceptional interest is that in which the incidence of disease is largely, though

not absolutely, restricted to one sex, and so far as is hitherto known the burden is generally borne by the male. Colour-blindness is a case in point, and as already mentioned (p. 111), the clue has been provided by *Drosophila*. Other examples of this form of inheritance are to be found in hæmophilia, in night-blindness (some pedigrees), in certain ocular defects, and in several diseases of the nervous system. The peculiar nature of the sex-limited inheritance finds its expression in pedigrees such as that

FIG. 52.

Pedigree of a hæmophilic family. Affected (all males) represented by black, and normals of both sexes by light circles. (From Stahel.)

illustrated in Fig. 52. In rare instances an affected female occurs as the result of a mating between an affected male and a female carrier. Such females mated with normal males produce affected sons only, while their daughters, being all heterozygous, are all carriers (cf. Fig. 36, p. 111).

Though by far the greater part of the human evidence relates to abnormal or diseased conditions, a start has been made in obtaining pedigrees of normal characters. From the ease with which it can be observed, it was natural that eye-colour should be early selected as a subject of investigation,

and the work of Hurst and others has clearly demonstrated the existence of one Mendelian factor in operation here. Eyes are of many colours, and the colour depends upon the pigment in the iris. Some eyes have pigment on both sides of the iris—on the side that faces the retina as well as on the side that looks out upon the world. Other eyes have pigment on the retinal side only. To this class belong the blues and clear greys ; while the eyes with pigment in front of the iris also are brown, hazel, or green in various shades according to the amount of pigment present. In albino animals the pigment is entirely absent, and as the little blood-vessels are not obscured the iris takes on its characteristic pinkish-red appearance. The condition in which pigment is present in front of the iris is dominant to that in which it is absent. Greens, browns, or hazels mated together may, if heterozygous, give the recessive blue, but no individuals of the brown class are to be looked for among the offspring of blues mated together. The blues, however, may carry factors which are capable of modifying the brown. Just as the pale pink-tinged sweet-pea (Pl. IV, 9) when mated with a suitable white gives only deep purples, so an eye with very little brown pigment mated with certain blues produces progeny of a deep brown, far darker than either parent. The blue may carry a factor which brings about intensification of the brown pigment. There are doubtless other factors which modify the brown when present, but we do not yet know enough of the inheritance of the various shades to justify any statement other than that the heredity of the pigment in front of the iris

behaves as though it were due to a Mendelian factor.

Even this fact is of considerable importance, for it at once suggests that the present systems of classification of eye-colours, to which some anthropologists attach considerable weight, are founded on a purely empirical and unsatisfactory basis. Intensity of colour is the criterion at present in vogue, and it is customary to arrange the eye-colours in a scale of increasing depth of shade, starting with pale greys and ending with the deepest browns. On this system the lighter greens are placed among the blues. But we now know that blues may differ from the deep browns in the absence of only a single factor, while, on the other hand, the difference between a blue and a green may be a difference dependent upon more than one factor. To what extent eye-colour may be valuable as a criterion of race it is at present impossible to say, but if it is ever to become so, it will only be after a searching Mendelian analysis has disclosed the factors upon which the numerous varieties depend.

A discussion of eye-colour suggests reflections of another kind. It is difficult to believe that the markedly different states of pigmentation which occur in the same species are not associated with deep-seated chemical differences influencing the character and bent of the individual. May not these differences in pigmentation be coupled with and so become in some measure a guide to mental and temperamental characteristics? In the National Portrait Gallery in London the pictures of celebrated men and women are largely grouped accord-

ing to the vocations in which they have succeeded. The observant will probably have noticed that there is a tendency for a given type of eye-colour to predominate in some of the larger groups. It is rare to find anything but a blue among the soldiers and sailors, while among the actors, preachers, and orators the dark eye is predominant, although for the population as a whole it is far scarcer than the light. The facts are suggestive, and it is not impossible that future research may reveal an intimate connection between peculiarities of pigmentation and peculiarities of mind.

The inheritance of mental characters is often elusive, for it is frequently difficult to appraise the effects of early environment in determining a man's bent. That ability can be transmitted there is no doubt, for this is borne out by general experience, as well as by the numerous cases of able families brought together by Galton and others. But when we come to inquire more precisely what it is that is transmitted we are baffled. A distinguished son follows in the footsteps of a distinguished father. Is this due to the inheritance of a particular mental aptitude, or is it an instance of general mental ability displayed in a field rendered attractive by early association? We have at present very little definite evidence for supposing that what appear to be special forms of ability may be due to specific factors. Hurst, indeed, has brought forward some facts which suggest that musical sense sometimes behaves as a recessive character, and it is likely that the study of some clean-cut faculty such as the mathematical one would yield interesting results.

The analysis of mental characters will no doubt be very difficult, and possibly the best line of attack is to search for cases where they are associated with some physical feature such as pigmentation. If an association of this kind be found, and the pigmentation factors be determined, it is evident that we should thereby obtain an insight into the nature of the units upon which mental conditions depend. Nor must it be forgotten that mental qualities, such as quickness, generosity, instability, etc.—qualities which we are accustomed to regard as convenient units in classifying the different minds with which we are daily brought into contact—are not necessarily qualities that correspond to heritable units. Effective mental ability is largely a matter of temperament, and this in turn is quite possibly dependent upon the various secretions produced by the different tissues of the body. Similar nervous systems associated with different livers might conceivably result in individuals upon whose mental ability the world would pass a very different judgment. Indeed, it is not at all impossible that a particular form of mental ability may depend for its manifestation, not so much upon an essential difference in the structure of the nervous system, as upon the production by another tissue of some specific poison which causes the nervous system to react in a definite way. We have mentioned these possibilities merely to indicate how complex the problem may turn out to be. Though there is no doubt that mental ability is inherited, what it is that is transmitted, whether factors involving the quality and structure of the nervous system itself, or factors involving the pro-

duction of specific poisons by other tissues, or both together, is at present uncertain.

Little as is known to-day of heredity in man, that little is of extraordinary significance. The qualities of men and women, physical and mental, depend primarily upon the inherent properties of the gametes which went to their making. Within limits these qualities are elastic, and can be modified to a greater or lesser extent by influences brought to bear upon the growing zygote, provided always that the necessary basis is present upon which these influences can work. If the mathematical faculty has been carried in by the gamete, the education of the zygote will enable him to make the most of it. But if the basis is not there, no amount of education can transform that zygote into a mathematician. This is a matter of common experience. Neither is there any reason for supposing that the superior education of a mathematical zygote will thereby increase the mathematical propensities of the gametes which live within him. For the gamete reckes little of quaternions. It is true that there is progress of a kind in the world, and that this progress is largely due to improvements in education and hygiene. The people of to-day are better fitted to cope with their material surroundings than were the people of even a few thousand years ago. And as time goes on they are able more and more to control the workings of the world around them. But there is no reason for supposing that this is because the effects of education are inherited. Man stores knowledge as a bee stores honey or a squirrel stores nuts. With man, however, the hoard is of a more lasting nature. Each generation in

using it sifts, adds, and rejects, and passes it on to the next a little better and a little fuller. When we speak of progress we generally mean that the hoard has been improved, and is of more service to man in his attempts to control his surroundings. Sometimes this hoarded knowledge is spoken of as the inheritance which a generation receives from those who have gone before. This is misleading. The handing on of such knowledge has nothing more to do with heredity in the biological sense than has the handing on from parent to offspring of a picture, or a title, or a pair of boots. All these things are but the transfer from zygote to zygote of something extrinsic to the species. Heredity, on the other hand, deals with the transmission of something intrinsic from gamete to zygote and from zygote to gamete. It is the participation of the gamete in the process that is our criterion of what is and what is not heredity.

Better hygiene and better education, then, are good for the zygote, because they help him to make the fullest use of his inherent qualities. But the qualities themselves remain unchanged in so far as the gamete is concerned, since the gamete pays no heed to the intellectual development of the zygote in whom he happens to dwell. Nevertheless, upon the gamete depend those inherent faculties which enable the zygote to profit by his opportunities, and, unless the zygote has received them from the gamete, the advantages of education are of little worth. If we are bent upon producing a permanent betterment that shall be independent of external circumstances, if we wish the national stock to become inherently

more vigorous in mind and body, more free from congenital physical defect and feeble mentality, better able to assimilate and act upon the stores of knowledge which have been accumulated through the centuries, then it is the gamete that we must consult. The saving grace is with the gamete, and with the gamete alone.

People generally look upon the human species as having two kinds of individuals, males and females, and it is for them that the sociologists and legislators frame their schemes. This, however, is but an imperfect view to take of ourselves. In reality we are of four kinds, male zygotes and female zygotes, large gametes and small gametes, and heredity is the link that binds us together. If our lives were like those of the starfish or the sea-urchin, we should probably have realised this sooner. For the gametes of these animals live freely, and contract their marriages in the waters of the sea. With us it is different, because half of us must live within the other half or perish. Parasites upon the rest, levying a daily toll of nutriment upon their hosts, they are yet in some measure the arbiters of the destiny of those within whom they dwell. At the moment of union of two gametes is decided the character of another zygote, as well as the nature of the population of gametes which must make its home within him. The union once effected the inevitable sequence takes its course, and whether it be good, or whether it be evil, we, the zygotes, have no longer power to alter it. We are in the hands of the gamete; yet not entirely. For though we cannot influence their behaviour we can nevertheless control their unions if we choose to do

so. By regulating their marriages, by encouraging the desirable to come together, and by keeping the undesirable apart we could go far towards ridding the world of the squalor and the misery that come through disease and weakness and vice. But before we can be prepared to act, except, perhaps, in the simplest cases, we must learn far more about them. At present we are woefully ignorant of much, though we do know that full knowledge is largely a matter of time and means. One day we shall have it, and the day may be nearer than most suspect. Whether we make use of it will depend in great measure upon whether we are prepared to recognise facts, and to modify or even destroy some of the conventions which we have become accustomed to regard as the foundations of our social life. Whatever be the outcome, there can be little doubt that the future of our civilisation, perhaps even the possibility of a future at all, is wrapped up with the recognition we accord to those who live unseen and inarticulate within us—the fateful race of gametes so irrevocably bound to us by that closest of all ties, heredity.

## APPENDIX

AS some readers may possibly care to repeat Mendel's experiments for themselves, a few words on the methods used in crossing may not be superfluous. The flower of the pea with its standard, wings, and median keel is too familiar to need description. Like most flowers it is hermaphrodite. Both male and female organs occur on the same flower, and are covered by the keel. The anthers, ten in number, are arranged in a circle round the pistil. As soon as they are ripe they burst and shed their pollen on the style. The pollen tubes then penetrate the stigma, pass down the style, and eventually reach the ovules in the lower part of the pistil. Fertilisation occurs here. Each ovule, which is reached by a pollen tube, swells up and becomes a seed. At the same time the fused carpels enclosing the ovules enlarge to form the pod. When this, the normal mode of fertilisation, takes place, the flower is said to be **selfed**.

In crossing, it is necessary to emasculate a flower on the plant chosen to be the female parent. For this purpose a young flower must be taken in which the anthers have not yet burst. The

keel is depressed, and the stamens bearing the anthers are removed at their base by a pair of fine forceps. It will probably be found necessary to tear the keel slightly in order to do this. The pistil is then covered up again with the keel, and the flower is enclosed in a bag of waxed paper until the following day. The stigma is then again exposed and dusted with ripe pollen from a flower of the plant selected as the male parent. This done, the keel is replaced, and the flower again enclosed in its bag to protect it from the possible attentions of insects until it has set seed. The bag may be removed in about a week after fertilisation. It is perhaps hardly necessary to add that strict biological cleanliness must be exercised during the fertilising operations. This is readily attained by sterilising fingers and forceps with a little strong spirit before each operation, thereby ensuring the death of any foreign pollen grains which may be present.

The above method applies also to sweet-peas, with these slight modifications. As the anthers ripen relatively sooner in this species, emasculation must be performed at a rather earlier stage. It is generally safe to choose a bud about three parts grown. The interval between emasculation and fertilisation must be rather longer. Two to three days is generally sufficient. Further, the sweet-pea is visited by the leaf-cutter bee, *Megachile*, which, unlike the honey bee, is able to depress the keel and gather pollen. If the presence of this insect is suspected, it is desirable to guard against the risk of admixture of foreign pollen by selecting for pollinating purposes a flower which has not quite opened. If the

standard is not erected, it is unlikely to have been visited by *Megachile*. Lastly, it not infrequently happens that the little beetle *Meligethes* is found inside the keel. Such flowers should be rejected for crossing purposes.

# TEXT-BOOK OF EMBRYOLOGY

VOL. II  
VERTEBRATA  
WITH THE EXCEPTION OF MAMMALIA

BY  
J. GRAHAM KERR

REGIUS PROFESSOR OF ZOOLOGY IN THE UNIVERSITY OF GLASGOW

## SPECIAL FEATURES

This work contains a large amount of matter which now appears in a Text-book for the first time.

It is the *first* exposition of the principles of Vertebrate Embryology which takes into account the Embryology of those peculiarly primitive Vertebrates (Polypterus, Lepidosiren, Protopterus) which have been worked out by the Glasgow School.

It contains a wealth of beautiful and in many cases original illustrations by Mr. Kirkpatrick Maxwell.

# TEXT-BOOK OF EMBRYOLOGY

VOL. I.—INVERTEBRATA

BY PROF. E. W. MACBRIDE, D.Sc., F.R.S.

"This work at once takes a place in the foremost rank of embryological studies. It will prove indispensable to all earnest students of zoology."—*The Lancet.*

"This book is one to be most warmly recommended to all naturalists."—*The Zoologist.*

"Professor MacBride has earned the gratitude of all English-speaking advanced students and teachers of embryology for this the best text-book in our language published since the appearance of Balfour's classical work some thirty-five years ago."—*Journal of Education.*
